INDEX

NAME INDEX

bbot (Dr. C. G.), Periodicities in Solar Variation—corrections, 414
ckers (Major C. P.), Private Estates and Forestry, 605
Adam (W. B.), [Miss Mamie Olliver and], "Vegetables as Food", 711
Adams, Jr. (Prof. N. I.), [Prof. L. Page and], Electrodynamics (*Review*), 398
Adburgham (J. F.), awarded a Chadwick prize, 145
Aiyappan (A.), Early Cult Figures from the Indus Valley, 360
iyar (Dr. H. S.), [Rev. O. R. Walkey and], Concise General Astronomy (*Review*), 11
Albert (Dr. A.), Dr. S. D. Rubbo and R. Goldacre, Correlation of Basicity and Antiseptic Action in an Acridine Series, 332; R. Goldacre and Dr. S. D. Rubbo, Further Correlation of Physical and Biological Properties in an Acridine Series, 709
bert (Prof. Eduard), Centenary of the birth of; work of, 85
xander (Dr. A. E.) and Prof. E. K. Rideal, A Possible New Approach to the Study of the Hydrogen Bond in Protein Structure, 541
xander (O. R.) and N. F. Hall, Heavy Oxygen, 361
ni (Father G.), [death], 201
en (R. M.), The Microscope (*Review*), 129
ison (Prof. I. S.), [Prof. W.H. Emmons, Prof. G. A. Thiel, Prof. C. R. Stauffer and], Geology: Principles and Processes. Second edition (*Review*), 556
ton (A. H. G.) and N. Y. Sandwith, Flora of South Albania, 82
ter (G.), Limits of Uniform Galactic Absorption, 810
derson (I. A.), [Dr. L. S. P. Davidson and; with Diet Sheets constructed by Miss Mary E. Thomson], A Textbook of Dietetics (*Review*), 312
derson (Sir John), Work of the Pharmaceutical Society, 506
derson (W.), [R. G. Carruthers and], Early Post-Glacial Conditions in England, 28
derson (W. A.), Population Increase in New York State, 124
drade (Prof. E. N. da C.), A Problem of Guthrie's Time (Guthrie Lecture); work of, 410
lrews (Prof. F. M.), [death], 505
drews (Dr. J. P.), J. A. Tomkins, 201
thony (Sylvia), The Child's Discovery of Death: a Study in Child Psychology (*Review*), 371
pleyard (F. N.) and Dr. C. G. Lyons, Practical Pharmaceutical Chemistry. Fourth edition (*Review*), 559
ber (Dr. Agnes), Tercentenary of Nehemiah Grew (1641–1712), 630
cell (Dr. W. J.), Mineral Resources of Continental Europe, 404, 443
nstrong (Dr. E. F.), The Mystery of Rust (*Review*), 307; Henry E. Armstrong (Armstrong Memorial Lecture), 373, 384; The Genesis of Printing Inks (*Review*), 589; The Spirit of Analysis (*Review*), 727
Arnold (Dr. R. N.), [Prof. W. Kerr, Dr. J. F. Shannon and], awarded the Thomas Lowe-Gray prize of the Institution of Mechanical Engineers, 295
non (Dr. D. I.), award of the 1,000 dollar prize of the American Association; work of, 292
Arraud (Dr. C. A.), Diathermie chirurgicale (*Review*), 10
hbaugh (R. P.), Protection of Buried Electrical Cables, 572
Askanazy (Prof. M.), [obituary article], 51
sprey (Dr. G. F.) and Dr. G. Bond, Respiration of Leguminous Root Nodules, 675
Astbury (Dr. W. T.) and Dr. Florence O. Bell, Nature of the Intramolecular Fold in Alpha-Keratin and Alpha-Myosin, 696
Aurousseau (M.), awarded the Peek Grant of the Royal Geographical Society, 478
Austin (Lord), [obituary article], 668
Austin (R. G.), Aids to Inorganic Chemistry (*Review*), 761
Aveling (Prof. F. A. P.), [death], 320
Avery (P.), [T. H. Goodspeed and], Trisomics in Nicotiana, 612
Avinery-Shapiro (S.), [Dr. J. Leibowitz and], Glycolysis, Hydrolysis and Phosphorolysis in *Corynebacterium diphtheriæ*, 745
Ayer (A. J.), The Foundations of Empirical Knowledge (*Review*), 287

Babcock [Keenan and], Reddening of Stars near the North Pole, 750
Bachelet (A. E.), Design of Wire Networks Carrying Radio Programmes, 802
Baddeley (J. F.), The Rugged Flanks of Caucasus. 2 Vols. (*Review*), 369
Badenhuizen (N. P.), Colchine-induced Tetraploids Obtained from Plants of Economic Value, 577
Bailey (Dr. E. B.), Introduction to Geology: General Geology (*Review*), 556
Bain (F. M.), Coco-nut Disease in Jamaica, 483
Baitsell (Prof. G. A.), Human Biology (*Review*), 494
Baker (Dr. E.), [death], 141
Baker (Dr. J. R.), Chlorazol Black *E* as a Vital Dye, 744
Baldwin (Miss B. M.), Metaphysics Rediscovered (*Review*), 7
Balfour of Burleigh (Lord), Supply and Price of Bread, 83
Balfour (Dr. J.), [death], 505
Baly (Prof. E. C. C.), Photosynthesis (*Review*), 97
Banet (L.), [Prof. F. Ehrenhaft and], Magnetization of Matter by Light, 297
Banting (Sir Frederick), [death], 260; [obituary article], 535
Bär (Prof. Richard), [obituary article], 536
Barclay (Dr. A. E.), C. Thurstan Holland, 259
Barcroft (Sir Joseph), Evolution of Function in the Mammalian Organism, 762
Barker (A. N.), appointed a temporary demonstrator in Sheffield University, 775
Barker (Prof. C. C.), Prof. E. L. Hirst and G. T. Young, Linkage between the Repeating Units in the Starch Molecule, 296
Barnes (Right Rev. Bishop), American Views on Modern Culture (*Review*), 367
Barnett (S. A.), G. Bourne and Dr. R. B. Fisher, Use of Silver Nitrate for the Histochemical Demonstration of Ascorbic Acid, 542
Barrett (Sir James), Youth Welfare in Australia, 671
Barringer (L. B.), Flight Without Power: The Art of Gliding and Soaring (*Review*), 38
Bartlett (Prof. F. C.), Fatigue Following Highly Skilled Work (Ferrier Lecture), 717
Bartlett (P. D.), [R. Wistar and], Coupling of Diazonium Salts, 679
Bartlett (R. J.), The Civilian Population under Bombardment, 700
Bateson (Mrs. Beatrice), [death], 636; [obituary article], 703
Baughan (Dr. E. C.), Heat of Hydration of the Proton, 30; Organic Bond Strengths and the Heat of Vaporization of Carbon, 542

Baynes (Dr. H. G.), Mythology of the Soul: a Research into the Unconscious from Schizophrenic Dreams and Drawings (*Review*), 74
Bayon (Dr. H. P.), A Medico-Psychological Revision of the Story of Jehanne La Pucelle, 23
Beale (Dr. G. H.) and Dr. A. C. Fabergé, Effect of Temperature on the Mutation Rate of an Unstable Gene in *Portulaca grandiflora*, 356
Beatty (Dr. R. T.), [obituary article], 770
Becking (Prof. L. G. M. Baas), in prison in Holland, 606
Beeck (O.), J. W. Givens and A. E. Smith, Long-Chain Polar Compounds in Lubrication, 613; A. E. Smith and A. Wheeler, Catalytic Activity and Structure of Metal Films, 646
Beer (A.), Variable Extent of the Atmosphere of Zeta Aurigæ, 30
Beeson (Dr. P. B.), Trichinosis in Britain, 774
Bell (A. E.), Early Work on Periodic Motion, 78
Bell (Dr. Florence O.), [Dr. W. T. Astbury and], Nature of the Intramolecular Fold in Alpha-Keratin and Alpha-Myosin, 696
Bell (R. P.), Physical Methods in Chemistry (*Review*), 159
Benesch (R.), Chemical Substitutes for Dietary Protein, 531
Bennet-Clark (T.) and D. Bexon, Water Relations of Plant Cells, 179
Bent (H. E.) and C. L. French, Ferric Thiocyanate, 715
Bentwich (Prof. N.), The Colonial Problem and the Federal Solution (*Review*), 461
Bergson (Prof. H.), refusal of exemption from the clauses of the new statute relating to Jews in France, 24; [death], 51; [obituary article], 168
Bernal (Prof. J. D.), Science and a New World Order, 143; The World in Unity and Struggle (*Review*), 187; The Physics of Air Raids, 594; D. Crowfoot, and I. Fankuchen, X-Ray Crystallography and Chemistry of the Steroids, 680
Berry (W. E.), [Y. V. Rao and], Carbohydrates in Apple Rootstocks, 150
Bessborough (Earl of), elected president of the Royal Sanitary Institute, 673
Best (Prof. C. H.), Sir Frederick Banting, 535
Beveridge (Sir William), appointed an under-secretary of the Ministry of Labour and National Service, 114; Peace by Federation? (*Review*), 461; Lord Stamp, 567
Bexon (D.), [T. Bennet-Clark and], Water Relations of Plant Cells, 179
Bhatnagar (S. S.) and D. L. Shrivastava, Immunity from Cellular Changes in the Blood, 58
Bibby (H. C.), appointed Education officer to the British Social Hygiene Council; work of, 262
Bidder (Dr. G. P.), Weighing Living Marine Animals, 328; re-elected president of the Marine Biological Association of the United Kingdom, 775
Biezeno (Prof. C. B.) und Prof. R. Grammel, Technische Dynamik (*Review*), 191
Bilham (P.) and Prof. G. A. R. Kon, Position of the Carboxyl Group in Oleanolic and Related Acids, 745
Bilmes (L.), [D. C. Broome and], Rheology of Plastic Materials, 176
Binns (A.), retiring president of the Institution of Mechanical Engineers; work of, 262
Birch (F.), Variation of Seismic Velocities within a Simplified Earth Model, 783; and H. Clark, Thermal Conductivity of Rocks, 301
Bishopp (D. W.), appointed director of the Geological Survey of Eire; work of, 202
Blackett (Prof. P. M. S.) and A. C. B. Lovell, Origin of Transient Ionic Clouds, 680
Blagden (Dr. J. W.) [obituary article], 19
Blair (Dr. G. W. Scott), Dr. S. J. Folley, F. M. V. Coppen and F. H. Malpress, Rheological Properties of Bovine Cervical Secretions during the Œstrous Cycle, 453
Blakemore (F.), Swine Influenza in Britain, 605
Blank (F.), [Prof. A. Frey-Wyssling and], Physiological Condition of Anthocyanins in Etiolated Seedlings, 148
Bledisloe (Viscount), Agriculture in Practice (*Review*), 520
Blewett (M.), [Dr. G. Fraenkel and], Deficiency of White Flour in Riboflavin, 716
Bliss (Prof. W. J. A.), [death], 260
Bloch (R.), [E. W. Sinnott and], Relative Position of Cell Walls in Developing Plant Tissues, 749
Bloomfield (G. F.) and E. H. Farmer, Rubber Fractions, 752
Blüh (Dr. O.), Science and Government, 299
Bodansky (Prof. Meyer and Dr. Oscar), Biochemistry of Disease (*Review*), 522
Bolliger (A.) and A. J. Canny, Renal Injury in *Trichosurus vulpecula* Produced by Œstrogens, 149
Bonacina (L. C. W.), Place of Scenery in the Study of the Weather and Climate, 203
Bond (Dr. G.), Biological Fixation of Nitrogen (*Review*), 789; [Dr. G. F. Asprey and], Respiration of Leguminous Root Nodules, 675
Booth (C. F.), Application and Use of Quartz Crystals in Telecommunications, 212
Booth (Prof. H. S.) and Prof. V. R. Damerell, Quantitative Analysis (*Review*), 525
Booth (V. H.), L. W. Mapson and Dr. T. Moore, "Vegetables as Food", 711
Born (Prof. Max), Diffuse Reflexion of X-Rays, 674
van den Bos (Dr.), appointed Union Astronomer; work of, 772
Bosanquet (Dr. W. C.), [obituary article], 231
Bosazza (V. L.), The Rarer Constituents of South African Fireclays, 747; Textures of Clays, 779
Bose (Dr. D. M.) and Miss Biva Chowdhry, Origin and Nature of Heavy Ionization Particles Detected on Photographic Plates Exposed to Cosmic Rays, 240
Boswell (Prof. P. G. H.), Stability of Minerals in Sedimentary Rocks, 734
Bottomley (W. T.), Condensing Plant for Power Stations, 683
Bourne (G.), [S. A. Barnett, Dr. R. B. Fisher and], Use of Silver Nitrate for the Histochemical Demonstration of Ascorbic Acid, 542
Bouwers (Dr. A.), Elektrische Höchstspannungen (*Review*), 11
Bower (Prof. F. O.), The Royal Botanic Gardens, Kew; Centenary as a Government Institution: History of the Gardens, 400
Bowman (Dr. A.), [death], 170; [obituary article], 320
Bowman (Dr. I.), awarded the Patron's Medal of the Royal Geographical Society, 478
Boyd (Mary M.), Corpus Luteum in Reptiles, 29
Boyland (Dr. E.), Work of the British Empire Cancer Campaign, 581
Bragg (Sir Lawrence), elected president of the Institute of Physics, 775
Bragg (Sir William), elected a trustee of the British Museum, 573
Braunholtz (H. J.), Bronze Head from Ifé, Nigeria, 270
Breslow (D. S.), [C. R. Hauser and], Coupling of Diazonium Salts, 680
Breuil (Prof. the Abbé H.), A Remarkable Painted Cave on the Estate of Leseaux (Montignac, Dordogne), 12, 21
Brierley (Prof. W. B.), Relationship of Pure and Applied Biology, 427
Brightman (R.), A Framework of World Co-operation (*Review*), 130; Federation and its Implications (*Review*), 461
Brink (R. A.) and D. C. Cooper, Development of the Seed in Angiosperms, 483
Briton-Jones (late Prof. H. R.), revised by Prof. E. E. Cheesman, The Diseases of the Coconut Palm (*Review*), 69
Britton (S. C.), awarded the Herbert Jackson prize of the L.M. & S. Ry., 387
Brode (R. B.), Magnet for Cosmic-Ray Cloud-Chamber Studies, 749
Brode (W. R.), and R. E. Brooks, Optically Active Dyes, 810
Broemser (Prof. P.), [death], 201
Brooks (C. S.) and M. E. Hobbs, Dipole Moments of Substituted Benzoic Acids, 91
Brooks (R. E.), [W. R. Brode and], Optically Active Dyes, 810

Broom (Dr. R.), Structure of the Sterkfontein Ape, 86; Mandible of a Young Paranthropus Child, 607
Broome (D. C.) and L. Bilmes, Rheology of Plastic Materials, 176
Brouwer (Dr. D.), promoted to a full professorship and appointed director of the Yale University Observatory, 355
Brown (A. M.), Alternation of Generations in Perennating Rust Fungi, 644
Brown (C. A. Cameron), Application of Electricity to Agriculture and Horticulture, 62
Brown (E. O. F.), [death], 703
Brown (H. C.), M. P. Kharasch and T. H. Chao, Reactions of Atoms and Free Radicals in Solution, 361
Brown (N. C.), [death], 601
Brown (W.), Control of Soil-borne Tomato Diseases, 354
Browning (Prof. C. H.), Landmarks in Chemotherapy (Bedson Lecture), 456
Browning (Dr. Ethel), Modern Drugs in General Practice (*Review*), 192
Bruce (C. E. R.), The Lightning and Spark Discharges, 805
Brunton (Dr. C. E.), Prof. J. S. Macdonald, 668
Bryant (S. A.), [W. G. Campbell and], Determination of *p*H in Wood, 357
Bullen (K. E.), Crustal Structure of New Zealand, 685
Bulloch (Prof. W.), [death], 201; [obituary article], 504
Burdon (Dr. R. S.), Surface Tension and the Spreading of Liquids (*Review*), 659
de Burgh (Prof. W. G.), Prof. G. Dawes Hicks, 381
Burgoyne (J. H.), Thermodynamic Properties of Propane, 579
Burkhardt (Dr. G. N.), Prof. A. Lapworth, 769
Burkill (A.), Prof. Henri Bergson, 168
Burn (Prof. J. H.), Pharmacology with Grace (*Review*), 593
Burnet (Dr. F. M.), Biological Aspects of Infectious Disease (*Review*), 74
Burr (H. S.), Field Properties of the Developing Frog's Egg, 780
Bushnell, jun. (D. I.), Early Man in Virginia, 476
Butler (Sir Edwin), resignation of the Secretaryship of the Agricultural Research Council, 265; work of, 506
Butler (E. G.), [O. E. Schotté and], Changes in Amputated Nerveless Limbs of Urodele Larvæ, 780
Butler (Dr. N. Murray), Our United States in this Backward Moving World, 113; True and False Democracy (*Review*), 518
Buxton (Prof. J. B.), Sir John McFadyean, 259
Buxton (Prof. P. A.), Control of Lice, 85; Relationship of Pure and Applied Biology, 427

Cadman (Lord), [death], 703; [obituary article], 798
Caley (J. F.), Natural Gas in Brantford Area, Ontario, 651
Callan (H. G.), Sex-Determination in the Earwig, 748
Calman (Dr. W. T.), Eales's Practical Histology and Embryology (*Review*), 495
Cameron (Dr. A. E.), The Effect of Felling on the Incidence of Forest Insect Pests, 507
Campbell (J. W.), Rocket Flight to the Moon, 235
Campbell (M. R.), [death], 505
Campbell (W. G.), [Prof. E. L. Hirst, Dr. G. K. N. Jones and], The ε-Galactan of Larch Wood, 25; S. A. Bryant, Determination of *p*H in Wood, 357
Cannon (Dr. Annie J.), [death], 474; [obituary article], 738
Cannon (H. G.), The Genus Gigantocypris, 179
Canny (A. J.), [A. Bolliger and], Renal Injury in *Trichosumus vulpecula* produced by Œstrogens, 149
Carington (W.), Experiments on the Paranormal Condition of Drawings (*Review*), 217
Carpenter (F. M.), Neuroptera of the Nearctic Region, 644
Carpenter (Prof. G. D. Hale), An Interesting Sidelight on the Causes of Coloration in Butterflies, 356
Carpenter (Prof. Rhys), The Vision of Ancient Life, 137
Carruthers (R. G.) and W. Anderson, Early Post-Glacial Conditions in England, 28
Carter (F. W. G.), Penguin Book of Food Growing, Storing and Cooking, 706
Casimir (H. B. G.), Magnetism and Very Low Temperatures (*Review*), 728
Cassie (A. M.), Making and Breaking Electrical Circuits (*Review*), 370
Cavell (A. C.), An Introduction to Chemistry. 3 parts (*Review*), 339
Challis (H. J. G.), Determination of Arsenic, 612
Chambers (E. G.), Statistical Calculation for Beginners (*Review*), 70
Champion (Dr. F. C.), University Physics. Part 2: Heat (*Review*), 728
Champion (Prof. H. G.), Forestry Administration (*Review*), 491
Chance (E. P.), The Truth About the Cuckoo (*Review*), 157
Chang (Y. L.), [S. S. Lu and], Structure of Vitreous Silica, 642
Chao (T. H.), [H. C. Brown, M. S. Kharasch and], Reactions of Atoms and Free Radicals in Solution, 361
Chapman (Capt. F. S.), awarded the Gill Memorial of the Royal Geographical Society, 478
Chapman (Prof. S.), awarded the Charles Chree medal and prize; work of, 261; Prof. Vito Volterra, 350; elected president of the Royal Astronomical Society, 387; Theory of Electrodynamics (*Review*), 398; The Sun as a Producer of Energy (Kelvin Lecture), 792
Chase (F. M.), Stimulation of Algal Growth by Ultra-Violet Radiation, 483
Chen (H. K.), H. Nicol and H. G. Thornton, Nodule Bacteria and their Hosts, 210
Chesney (Lt.-Col. C. H. R.), with four chapters by J. Huddlestone, The Art of Camouflage (*Review*), 758
Chichester (F.), The Observer's Book on Astro-Navigation. 2 parts (*Review*), 493
Chick (Dr. Harrietta), The Nutrition Value of the Potato, 103
Childe (Prof. V. Gordon), Prehistoric Communities of the British Isles (*Review*), 337
Childs (Dr. E. C.), Science and Government, 298
Chowdhry (Miss Biva), [Dr. D. M. Bose and], Origin and Nature of Heavy Ionization Particles Detected on Photographic Plates Exposed to Cosmic Rays, 240
Christie (W. H.), Zeta Aurigæ, 180
Churchill (Mr. Winston), elected a fellow of the Royal Society; interest in scientific developments, 704; admission of, into the fellowship of the Royal Society, 772
Clark (Prof. C. C.), and R. H. Hall, This Living World: a College Course in Science (*Review*), 761
Clark (H.), [F. Birch and], Thermal Conductivity of Rocks, 301
Clarke (G. R.), The Study of the Soil in the Field. Third edition (*Review*), 761
Clarke (R. W. B.), Britain's Blockade, 234
Claughton (H.), appointed acting-principal of London University, 355
Clausen (Dr. S. W.) and others, Alcohol and Vitamin A, 323
Clay (R. C.), K. Cook and J. I. Routh, Composition of Human Hair, 30
Clayton (Capt. P. A.), awarded the Founder's medal of the Royal Geographical Society, 478
Clemmesen (Dr. J.), Cancer and Occupation in Denmark, 741
Clifford (Sir Charles), bequest to Sheffield University, 775
Clifford (E. H.), elected president of the Institution of Mining and Metallurgy; work of, 171
Cobham (Sir Alan), Flight Refuelling, 172
Cohan (L. H.) and G. E. Meyer, Properties of Liquids in Small Capillaries, 61
Cole (Prof. F. J.), The University of Leyden: Contributions to Biology and Medicine, 161
Cole (H. A.), Sex-Ratio in *Uralpinx cinerea*, the American Oyster Drill, 116
Colhoun (J.), [A. E. M. Muskett and], Prevention of Stem-Break, Browning and Seedling Blight in the Flax Crop, 176
Collinge (Dr. W. E.), Weather, Wild Birds and Home-grown Food, 267
Collingwood (Prof. R. G.), An Essay on Metaphysics (*Review*), 7

Conant (Prof. J. B.), conferment upon, of an honorary doctorate by Oxford University, 355; elected a foreign member of the Royal Society; work of, 704
Connelly (W.), Dr. G. E. Vincent, 229
Conway (Prof. E. J.), Palæochemistry of the Ocean, 480; Physiological Origins of Cellular Potassium, 574
Conway (Dr. V. M.), appointed an assistant lecturer in Sheffield University, 775
Cook (Prof. J. W.), Bile Acids of Elasmobranch Fish, 388; [Dr. E. L. Kennaway and], awarded the Katherine Berkan Judd prize, 573
Cook (K.), [R. C. Clay, J. I. Routh and], Composition of Human Hair, 30
Cook, Hewett, Kennaway and Kennaway, Substances producing Cancer of the Liver in Mice, 419
Cook (W. H.) and W. H. White, Rancidity of Pork and its Prevention, 644
Cooke (H. B. S.), Prof. C. van Riet Lowe and L. H. Wells, Geology and Early Man, 45
Cooper (Sir Astley), centenary of the death of; work of, 173
Cooper (D. C.), [R. A. Brink and], Development of the Seed in Angiosperms, 483
Copley (G. N.), Viscosities of Three Classes of Liquids, 207
Coppen (F. M. V.), [Dr. G. W. Scott Blair, Dr. S. J. Folley, F. H. Malpress and], Rheological Properties of Bovine Cervical Secretions during the Œstrous Cycle, 453
Corner (E. J. H.), Wayside Trees of Malaya. 2 Vols. (*Review*), 6; Occurrence of Larger Fungi in the Tropics, 450
Cornu (Marie-Alfred), centenary of the birth of; work of, 265
Coulson (A. L.), Underground Water Supply of Calcutta, 612
Coursey (P. R.), Electrolytic Condensers: their Properties, Design, and Practical Uses. Second edition (*Review*), 74
Cox (Dr. H. R.), awarded the Theobald Smith bronze medal and award, 451
Crawford (L.), elected president of the Royal Society of South Africa, 85
Crompton (J.), [death], 739
Crossland (Dr. C.), Red Sea Corals, 644
Croucher and Mitchell, Banana Fertilizer Investigations in Jamaica, 618
Crowfoot (D.), [Prof. J. D. Bernal, I. Fankuchen and], X-Ray Crystallography and Chemistry of the Steroids, 680
Crowther (Dr. C.), The Feeding of Livestock (*Review*), 587
Crowther (Prof. J. A.), Science and Government, 415; Stars and Atoms (*Review*), 689
Crowther (J. G.), A History of Mycology (*Review*), 279
Cruttwell (Dr. C. R. M. F.), [death], 382
Cullis (Prof. C. G.), [death], 536; [obituary article], 636
Curie (Mlle. Eve), deprived of French citizenship and confiscation of property, 573
Curtis (Miss Myra), elected principal of Newnham College, Cambridge, 775
Curwen (E. C.), Origin of the Pentatonic Scale, 90
Cutler (D. Ward), [obituary article], 200

Dakin (Prof. W. J.), Plankton of the Australian Coastal Waters off N.S.W., part 1; work of, 705
Dale (W. M.), X-Rays and Enzymes, 271
Damerell (Prof. V. R.), [Prof. H. S. Booth and], Quantitative Analysis (*Review*), 525
Dantzig (Prof. T.), Number: the Language of Science. Second edition (*Review*), 9
Darlington (Dr. C. D.), The Cleavage in Biology, 544; and M. B. Upcott, Spontaneous Chromosome Change, 301; M. B. Upcott, Inert Chromosomes, 713
Darrow (K. K.), New Instruments in Physics, 539
Davenport (Dr. C. B.), Early Growth of the Human Skull, 90
Davenport (Dr. H.), awarded the Adams prize of Cambridge University, 708
David (Prof. W. T.), Temperature and Latent Energy in Flame Gases, 89; and Dr. A. S. Leah, awarded the Starley premium of the Institution of Mechanical Engineers, 295
Davidson (Sir Andrew), appointed chief medical officer of the Scottish Department of Health, 237
Davidson (Dr. L. S. P.) and I. A. Anderson, with Diet Sheets constructed by Miss Mary E. Thomson, A Textbook of Dietetics (*Review*), 312
Davie (T. B.), [L. Oakes and], A Pocket Medical Dictionary. Fourth edition (*Review*), 10.

TITLE INDEX

Abyssinian Ornithology, 292
Accra Earthquake of 22nd June, 1939, Dr. N. R. Junner and others, 751
Acoustical Engineering, Elements of, Dr. H. F. Olsen (*Review*), 311
Acridine Series: Basicity and Antiseptic Action in an, Correlation of, Dr. A. Albert, Dr. S. D. Rubbo and R. Goldacre, 332; Further correlation of Physical and Biological Properties in an, Dr. A. Albert, R. Goldacre and Dr. S. D. Rubbo, 709
Adenylpyrophosphate, Myosin Birefringence and, Dr. J. Needham, Dr. Shih-Chang Shen, Dr. Dorothy M. Needham and Dr. A. S. C. Lawrence, 766
Adiabatic Compressibility, Temperature Dependence of, M. Rama Rao, 268
Administration: Scientific, in National and Local Government, 489; Regionalism in, 619
Adsorption, Some Problems in, J. K. Roberts (*Review*), 728
Adventure, I married (*Film*), 670
Aerial: Attack, Terrorism in, 602; Warfare, Present-day (*Review*), 657
Aeroplane, The Military, E. C. Shepherd (*Review*), 657
Africa: Forestry in, 63; Focus on, Dr. R. U. Light (*Review*), 757
African Survey, Lord Hailey (*Review*), 757
Agricultural: Research Council, resignation of Sir Edwin Butler, 265, 506; Policy in Great Britain, 447; Prof. W. W. C. Topley appointed secretary of the, 478, 506; Testament, An, Sir Albert Howard (*Review*), 590; Laboratories, Regional, in the United States, Dr. R. O. Whyte, 597; Land and National Planning, Dr. L. Dudley Stamp, 647; Uganda, Production in, J. H. Holland (*Review*), 691; Improvement Council for England and Wales, appointment of an, 775
Agriculture: and Horticulture, Application of Electricity to, C. A. Cameron Brown, 62; Electricity in, H. W. Grimmitt, 93; in Practice, Viscount Bledisloe (*Review*), 520; Sources of Information on, 671; in Uganda, Edited by Dr. J. D. Tothill (*Review*), 691; British, Intensification of, Sir John Russell (*Review*), 760
Air: Raid Damage, 20, 53, 111, 112; to the London Museum, 323; Conditioning, Trends in, 449; Navigation (*Review*), 493; Council, Sir Henry Tizard appointed an additional member of the, 740; Raids, The Physics of, Prof. J. D. Bernal, 594.
Aircraft Engines, Vol. 1. A. W. Judge (*Review*), 158: Power Units for (*Review*), 158; Production, 537; Metals, Effect of Low Temperatures on, S. J. Rosenberg, 605; Supply Council, Air Vice-Marshal F. J. Linnell appointed a member of the, 740; Airscrew, New type of, 602
Alaska, Ipiutak on Point Hope, Reported Discovery of a Prehistoric Civilization at, 540
Albania, South, Flora of, A. H. G. Alston and N. Y. Sandwith, 82
Alcohol: and Vitamin A, Dr. S. W. Clausen, B. B. Breeze, W. S. Baum, A. B. McCoord and J. O. Rydeen; Dr. L. B. Pett, 323; and Brain Metabolism, Drs. W. W. Goldfarb, K. M. Bowman and J. Wortis, 324
Aldehydes, Reagent of, F. G. Singleton and C. B. Pollard, 613
Algal Growth, Stimulation of, by Ultra-Violet Radiation, F. M. Chase, 483
Alloys, Age-hardening, Pre-precipitation Phenomena in, F. W. Jones and P. Leech, 327
Aluminium and its Alloys, The Anodic Oxidation of, Dr. A. Jenny. Trans. by Winifred Lewis (*Review*), 659
America and Siberia, Anthropological Connexions between, Dr. A. Hrdlička, 748
American: Central, Plants, P. C. Standley and J. A. Steyermark, 29; Social Hygiene Association, award of the Snow medal to Mrs. Neville-Rolfe, 114; Natural History Museum, Activities of the, 203; Association, award of the 1,000 dollar prize of the, to Dr. D. I. Arnon, 292; Geographical Society, award of the Cullum geographical medal to Dr. R. C. Murphy and of the Charles P. Daly medal to Prof. C. O. Sauer, 294; Message, An, P. B. Findley, P. C. Jones, F. L. Hunt, E. L. Shepherd and A. R. Thompson, 329; Association, Dr. I. Langmuir elected president of the, 352; Chemical Society, Prof. E. A. Doisy awarded the Willard Gibbs medal of the Chicago Section of the, 355; Philosophical Society: gift of the, to the Royal Society for the aid of Science in Britain, 414; Publications of the, 509; Message to British Zoologists, 571; Chemical Society, award of the Priestley medal of the, to Dr. T. Midgley, jun., 606; Society of Plant Physiology, award of the Stephen Hales prize of the, to Dr. P. R. White, 639; Philosophical Society, Sir D'Arcy Thompson elected a member of the, 775; Physiological Society, gift to the Royal Society for the support of British scientific publications, 804
Amphibia, Pigmentary Changes and the Background Response in, Dr. B. Dawes, 806
Analysis, The Spirit of, Dr. E. F. Armstrong (*Review*), 727
Analytical Processes: a Physico-Chemical Interpretation, Dr. T. B. Smith (*Review*), 495; Ancient Life, The Vision of, Prof. Rhys Carpenter, 137
Angiosperms, Seed in, Development of the, R. A. Brink and D. C. Cooper, 483
Anglo-American Collaboration for Democracy, 517
Animal: Behaviour, Elementary, Dr. E. S. Russell (*Review*), 190; Breeds, Names of, Legal Protection of the, Dr. T. M. Olbrycht, 238
Animals: The Orientation of, Kineses, Taxes and Compass Reactions, Dr. G. S. Fraenkel and Dr. D. L. Gunn (*Review*), 190; in Action, Dr. G. Pickwell (*Review*), 659
Anions, Water and, Oxygen Exchange between, G. A. Mills, 30
Anthocyanins in Etiolated Seedlings, Physiological Condition of, Prof. A. Frey-Wyssling and F. Blank, 148
Antibodies, Structure and Formation of, A Theory of the, L. Pauling, 60
Antirrhinums, Rust-resistant, D. E. Green, 611
Antler Growth, Sesame Cake and, Prof. J. C. Drummond, Dr. A. W. Greenwood, R. R. Ridgway and P. C. Williams, 26
Anuran Parasites, M. M. Metcalf, 29
Apache-Pueblo Culture Elements, E. W. Gifford, 120
Apodemus, Sex Chromosomes of, P. C. Koller, 645
Apple: Rootstocks, Carbohydrates in, Y. V. Rao and W. E. Berry, 150; Fruit, Morphology of the, Prof. L. H. MacDaniels, 180; Cortex, Structure of the, W. H. Smith, 210
Apples: Skin Coatings on, Effect of, Dr. S. A. Trout, R. N. Robertson, E. G. Hall and Frances Hackney, 27; Australian, Storage of, Trout, Tindale and Huelin, 652
Aquilegia, Genetics of, B. Schafer, 578
Arabs, The, Prof. H. A. R. Gibb, 234
Argentine: Republic, Provisional Vital Statistics of the, for 1938, 174; and Patagonia, the Grasslands of the, W. Davis, 477

Armstrong, Henry E., Dr. E. F. Armstrong (Armstrong Memorial Lecture), 373, 384
A.R.P. Communication, W. P. Wilson, 92

Caffelite: a new plastic, 672

Calcutta, Underground Water Supply of, A. L. Coulson, 612

Cambridge: University, Physiology at, presentation to W. Freeman, 22; Sons of, Prof. F. J. M. Stratton (*Review*), 189; University: Molteno Institute, continue of grant by the Rockefeller Foundation, 265; bequest to, by Dr. C. Slater, 673; election of Dr. J. A. Venn as Vice-Chancellor; award of the Adams prize to Dr. H. Davenport, 708; Newnham College, impending retirement of the principalship of, by Miss J. P. Strachey; Miss Myra Curtis elected principal, 775

Camouflage: in Warfare, Sir John Graham Kerr (*Review*), 758; The Art of, Lt.-Col. C. H. R. Chesney. With four chapters by J. Huddlestone (*Review*), 758

Campbeltown Raised Beach, The, and its Contained Stone Industry, Dr. W. J. McCallien and A. D. Lacaille, 422

Canada: Marine Animal Oils of, Prof. T. P. Hilditch, 548; Engineering Institute of: presentation of the Sir John Kennedy medal of the, to Lt.-Genl. A. G. L. McNaughton, 606; Research in, Lt.-Genl. A. G. L. McNaughton, 626; Telephones in, 639

Canadian Polar Year Expeditions, Vol. I, 508

Cancer, Leukæmia and Allied Tumours: The Periodicity of, with Chapters on their Treatment, Dr. J. H. D. Webster (*Review*), 68; of the Liver in Mice, Substances Producing, Cook, Hewett, Kennaway and Kennaway, 419; and Occupation in Denmark, Dr. J. Clemmesen, 741

Cannabinol, Synthesis of, R. Ghosh, A. R. Todd and S. Wilkinson, 121

Cantabrigienses, Alumni, Dr. J. A. Venn, Part 2: from 1752 to 1900, Vol. I (*Review*), 189

Carbon: Dioxide, Hydration of, and the Stability of Hypochlorite Aerosols, P. V. Youle, 59; Monoxide, Flame Spectrum of, A. G. Gaydon, 301; Dioxide in Air, Estimation of, Prof. H. Dingle and A. W. Pryce, 331; Organic Bond Strengths and the Heat of Vaporization of, Dr. E. C. Baughan, 542; Dioxide Assimilation in Heterotrophic Organisms, Dr. H. A. Krebs, 560

Carbonyl Compounds, Resolving Agent for, R. B. Woodward, T. P. Kohman and G. C. Harris, 646

Card Guessing, Fresh Light on, S. G. Soal (*Review*), 217

Cardiff University College, Air Raid Damage to, 384

Carnegie: Corporation of New York, Report, Sept. 30, 1940, 233; Trust for the Universities of Scotland, Thirty-ninth Annual Report of the, 570; Institution of Washington, Year Book No. 39, 650

Caroline Medical Institute, Stockham, Addition of a Neurological Section, 145

Carrot as Food, The, 132

Caucasus, The Rugged Flanks of, J. F. Baddeley. 2 Vols. (*Review*), 369

Caytonia: a gymnosperm, Prof. T. M. Harris, 270; Microsporophylls of, Prof. T. M. Harris, 678

Celtic Linch Pin, A, 300

Ceylon, The Stone Age and Cave Men of, P. E. P. Deraniyagala, 392

Chadwick Prizes, Award of, to P. O. Reece, Dr. S. L. Wright and J. F. Adburgham, 145

Chambers's Technical Dictionary, edited by C. F. Tweeney and Dr. L. E. C. Hughes (*Review*), 372

Charred Documents, Decipherment of, A New Method for the, W. D. Taylor and H. J. Walls, 417; G. A. Jones, 676

Chemical: Literature, Utilization of (*Review*), 310; Publications: their Nature and Use, Prof. M. G. Mellon (*Review*), 310; "Chemical Publications", Prof. M. G. Mellon, re review of,—a correction, 355; Engineers, Institution of, awards presented to M. B. Donald, J. C. Farrant, S. A. Gregory and J. V. S. Glass, 451; Industries, Post-War Problems for, F. Heron Rogers, 538; Analysis, Qualitative, A Text-Book of, Dr. A. I. Vogel. Second Edition (*Review*), 727; Science, An Introduction to, Prof. W. H. Hatcher (*Review*), 790

Chemicals, Fine, Preparation of, 353

Chemistry: Applied, Thorpe's Dictionary of late Sir Jocelyn Field Thorpe and Dr. M. A. Whiteley. Fourth Edition, Vol. 4 (*Review*), 39; Physical: Organic, Reaction Rates, Equilibria and Mechanisms, Prof. L. P. Hammett, (*Review*), 101; An Introduction, Dr. E. A. Moelwyn-Hughes (*Review*), 159; Methods in, R. P. Bell (*Review*), 159; Institute of, Report of the; Dr. J. J. Fox re-elected President; Award of the Meldola Medal to Dr. E. R. H. Jones, 294; Applied, for Engineers, Dr. E. S. Gyngell (*Review*), 312; A School (*Review*), 339; An Introduction to, A. C. Cavell, 3 parts (*Review*), 339; Pharmaceutical, Practical, F. N. Appleyard and Dr. C. G. Lyons. Fourth Edition (*Review*), 559; Inorganic, Aids to, R. G. Austin (*Review*), 761; Everyday (*Review*), 790; Organic, Elimination Reactions in, Mechanism, M. L. Dhar, Dr. E. D. Hughes, Prof. C. K. Ingold, A. M. M. Mandour, F. R. Webb and L. I. Woolf, 812; Tautomerism and Elimination, Dr. E. D. Hughes, 813

Chemotherapy, Landmarks in, Prof. C. H. Browning (Bedson Lecture), 456

Cherries, Origin of, T. Raptopoulos, 809

Cheviot Granite, The A. G. Jhingran, 211

Chiasma Interference, H. B. Newcombe, 713

Chiltern Country, H. J. Massingham (*Review*), 372

Chi-Square Test of Goodness to Fit, A Detailed Proof of the, E. R. Greenhood, Jr. (*Review*), 70

Chlorazol Black *E* as a Vital Dye, Dr. J. R. Baker, 744

Chree, Charles, Medal and Prize, award of the, to Prof. S. Chapman, 261

Chromatid Interference, C. L. Huskins and H. B. Newcombe, 645

Chromosome Studies, T. S. Painter, 120; Change, Spontaneous, Dr. C. D. Darlington and M. B. Upcott, 301

Chromosomes, Inert, Dr. C. D. Darlington and M. B. Upcott, 713

Civics, The Task of, 173

Civil: Defence, Leadership in, 95; List Pensions, 509; Defence, Organization of, 721

Civilian Population, the, under Bombardment, R. J. Bartlett, 700

Clay Minerals in Soil Mortars, Detection of, by Photoelectric Cell, Dr. B. H. Knight, 27

Clays, Textures of, V. L. Bosazza, 779

Clinicians and Biochemists (*Review*), 522

Coal, Underground gasification of, in the U.S.S.R., 477; Geology of: O. Stutzer. Translated and revised by the late Dr. A. C. Noé; Dr. N. Macgregor (*Review*), 521

Coconut: Diseases, Prof. C. W. Wardlaw (*Review*), 69; Palm, the Diseases of the, late Prof. R. H. Briton-Jones, revised by Prof. E. E. Cheesman (*Review*), 69; disease in Jamaica, F. M. Bain, 483

Collaboration in Europe, 1

Colonial: Office Appointments, 145; 205; 325; Problem: the, and the Federal Solution, Prof. N. Bentwich (*Review*), 461; Administration, E. R. J. Hussey (*Review*), 591; Office Appointments, 606

Colonies, Secretary of State for the, Lord Moyne appointed, 202

Colonsay, Age of the Monchiquite Dykes of, W. D. Urry and Prof. A. Holmes, 714

Colour: Temperature Scales; International comparison of, Dr. R. C. Williams, 180; Tolerance: R. F. Wilson; H. W. Ellis, J. W. Perry, 303; Measurement: Psychological Aspects of, Dr. H. J. Eysenck, 682

Coloured Light Signals, Recognition of, J. G. Holmes, 423

Combustion, Power and, Prof. A. C. G. Egerton (Thomas Hawksley Lecture), 122

Comet Cunningham, 24; 715

Comets, 386, 387

Commonwealth Solar Observatory, Canberra, Report of, May 1939—April 1940, 55

Computation, Scientific, Punched Card Methods in, W. J. Eckert (*Review*), 131

Condensing Plant for Power Stations, W. T. Bottomley, 683

Congo, Divination on the, T. Delachaux, 179

Conjugated Systems, A Property of, Prof. J. Kenner, 482
Co-operation ; International, a basis of, 245 ; basis of, Science, National and International, and the, Prof. A. V. Hill, 250
Coopers Hill War Memorial Prize and Medal, J. S. Forrest awarded the, 174
Copper Sulphide, Activated, Catalysis by, Dr. A. Wassermann, 391 ; Pyrites, Dependence of the Direction of Rectification in, on Voltage, Temperature and Time of Measurement, M. A. El-Sherbini and Y. L. Yousef, 543 ; in Ore Deposits, Source of, C. H. White, 679
Coq d'Or, Le, 785
Corn : Country, C. H. Warren (*Review*), 310 ; Growing in the Old Days, Sir John Russell (*Review*), 310
Corona, Periodicity in the, K. G. Meedahl, 61
Corpus Luteum in Reptiles, Mary M. Boyd, 29
Corrosion of Iron and Steel, The, Dr. J. C. Hudson (*Review*), 307 ; of Iron and Steel in Sea Water, 343
Corynebacterium diphtheriæ, Glycolysis, Hydrolysis and Phosphorolysis in, Dr. J. Leibowitz and S. Avinery-Shapiro, 745
Cosmic : Ray Showers, Penetrating, Dr. L. Jánossy, 56 ; Radiation at high latitudes, Asymmetry of, F. G. P. Seidl, 579 ; Ray Cloud-Chamber Studies, Magnet for, R. B. Brode, 749 ; -Ray Intensity, Temperature and Variations of, A. Duperier, 781
Counting, From, to the Continuum, Prof. J. B. S. Haldane (*Review*), 9
Crime : and the Man, Prof. E. A. Hooton (*Review*), 656 ; Relation of, to Nation and Race, Sir Arthur Keith (*Review*), 656
Criminal : The American, and Anthropological Study, Prof. E. A. Hooton (*Review*), 656
Cromer Forest Bed, Industries of the, J. Reid Moir, 530
Crustal Structure of New Zealand, K. E. Bullen, 685
Crystal Lattices, Stability of, R. Fürth, 613
Crystalline Copper Sulphate, Magnetic and Thermal Properties of, at low temperatures, Prof. K. S. Krishnan, 87
Crystals and Photons, Sir C. V. Raman, 485
Cuckoo : The Behaviour of the, Dr. F. H. A. Marshall (*Review*), 157 ; The Truth about the, E. P. Chance (*Review*), 157 ; Cultural Diffusion : Fiction and Fact in, M. B. Emeneau and Dr. D. G. Mandelbaum, 60 ; Relationships, International, 277
Culture : Modern, American Views on, Rt. Revd. Bishop Barnes (*Review*), 367 ; To Hell with, Democratic Values are New Values, H. Read (*Review*), 621
Cyclotron : new, at Berkeley, California, 22 ; a 50-million volt, to be built in Moscow, 114
Cylinder Wear, Collected Researches on, C. G. Williams (*Review*), 691
Cyrenaica : Culture and Antiquities, 223
Czechoslovakia : Twenty years of Independence, Prof. R. J. Kerner, 412

Dairy Science, Some recent advances in, Prof. H. D. Kay, 42 ; (*Review*), 75
Dam Construction in the Tennessee Valley, 153
Dams and the Problem of Migratory Fishes, 485
Dark Adaptation, Effect of Caffeine and Bromide on, Prof. R. W. Ditchburn and E. J. P. Steele, 745
Death : Children's Ideas of, Dr. R. H. Thouless (*Review*), 371 ; The Child's Discovery of, a Study in Child Psychology, Sylvia Anthony (*Review*), 371
Decapod Crustacea, Photophores of some, On the structure of the, Dr. R. Dennell, 515
Democracies : Aid to the, President Roosevelt, 351 ; The, and Honour, 537
Democracy : United, President Roosevelt, 20 ; Anglo-American Collaboration for, 517 ; The Moral Basis of, Mrs. Eleanor Roosevelt (*Review*), 518 ; True and False, Dr. N. Murray Butler (*Review*), 518
Democratic Ideal, the United States and the, President Roosevelt, 142
Dental Caries, Diet in relation to, Prof. E. V. McCollum, 104
Desertic Conditions, Spread of, E. J. Wayland, 85
Developmental Systems, Evolution of, Dr. C. H. Waddington, 108
Diagnosis, Modern, Edited by Sir Humphry Rolleston and Dr. A. Moncrieff (*Review*), 495
Diamond : Diffuse Reflections from, Dr. H. A. Jahn and Dr. K. Lonsdale, 88 ; Quantum X-Ray Reflection in, Sir C. V. Raman and Dr. P. Nilakantan, 118
Diathermie chirurgicale, Dr. C. A. Arraud (*Review*), 10
Diazonium Salts, Coupling of, R. Wistar and P. D. Bartlett, 679 ; C. R. Hauser and D. S. Breslow, 680
Diet in relation to Dental Caries, Prof. E. V. McCollum, 104
Dietary Protein : Chemical Substitutes for, R. Benesch, 531 ; E. C. Owen, J. A. B. Smith and Dr. N. C. Wright, 710
Dietetics, A Textbook of, Dr. L. S. P. Davidson and I. A. Anderson ; with Diet Sheets constructed by Miss Mary E. Thomson (*Review*), 312
Diphtheria, Hypertoxic, the Problem of, Dr. G. F. Petrie, 182
Disease, The Control of, T. H. Hawkins (*Review*), 99
Dordogne, Palæolithic Paintings in the, Prof. the Abbé Breuil, 11, 21
Drawings, Paranormal Condition of, Experiments on the, W. Carington (*Review*), 217
Drosophila melanogaster : Ultra-violet Absorption by, E. Durand, A. Hollaender and M. B. Houlahon, 809 ; Wing Development in, A. D. Lees, 809
Drug : Plants, British, 21 ; Supplies in War-time, A. Mortimer, 112 ; Therapy, Modern (*Review*), 192
Drugs : Modern, in General Practice, Dr. Ethel Browning (*Review*), 192 ; in War-time, Economy in the use of, 323 ; within the British Empire, Production of, 393
Dyes, Optically Active, W. R. Brode and R. E. Brooks, 810
Dyke-Sill Intrusion in the Transvaal, A closed, J. Ellis, 713
Dynamics, Technical, Prof. L. M. Milne-Thomson (*Review*), 191
Dynamik, Technische, Prof. C. B. Biezeno and Prof. R. Grammel (*Review*), 191

Early Cult Figures from the Indus Valley, A. Aiyappan, 360 ; Man in Virginia, D. I. Bushnell, Jr., 476
Earth and Moon : Figures of the, Dr. H. Jeffreys, 484 ; Ellipticities of the, Dr. H. Jeffreys, 613
Earthquake : in Cyprus, 145 ; 174 ; in Greece, 292 ; near New Guinea, 414 ; in Western Japan, 478 ; in Mexico, 507 ; South Atlantic, of 28th August, 1933, The Love Waves of the, J. T. Wilson, 578 ; in Manchuria, 606 ; in Atlantic Ocean, 639 ; North Pacific, of Nov. 10, 1938, F. J. de Lisle, 713 ; Accra, of 22 June, 1939, Dr. N. R. Junner and others, 751 ; Waves, Velocities of, 783 ; in Baja, California, 804
Earthquakes : Recent, 24 ; 114 ; 174 ; Deep-Focus, of the South-West Pacific, R. C. Hayes, 213 ; Recent, recorded at Kew, 414 ; near America, 450 ; Recent, recorded at Kew, 508 ; recorded at Kew, 540 ; recorded in Switzerland, 540 ; in Spain, 673 ; in Turkey, 708 ; registered at Kew, 804
Earth's Figure, Gravity Anomalies and the, 273
Earwig, Sex-Determination in the, H. G. Callan, 748
Economic : Policy and Man Power, 185 ; Plan, Outline of a Long-Term, W. L. Fairweather, 476 ; Policy to-day and to-morrow, 687
Edinburgh University, Institution in, of a Polish School of Medicine, 112
Education : as a National Asset, 125 ; of the Future, R. Weatherall (*Review*), 725 ; The Future in, Sir Richard Livingstone (*Review*), 725
Educational : Policy, Population Problems and, 305 ; Yearbook of the International Institute of Teachers College, Columbia University, 1940, Edited by Prof. I. L. Kandel (*Review*), 555
Egyptian Calendar, Ancient, Origin of the, H. E. Winlock, 31
Eire : Geological Survey of, D. W. Bishopp appointed Director of the, 202 ; Emergency Research Bureau in, 384 ; State Chemist of, Report for year ending March 31, 774

Elastic Solid, Finite Deformations of an, F. D. Murnaghan, 784
Electric: and Magnetic Fields, Stationary, in Beams of Light, Prof. F. Ehrenhaft, 25; Discharge Lamps, Dr. C. C. Paterson, 333; Supply in Churches, 508; Heating of Beehives, E. B. Wedmore, 549; Ship, The, A. C. Hardy, 707
Electrical: Plant and Associated Problems, the Commissioning of, R. C. H. Richardson (*Review*), 10; *Engineers, Institution of, Journal of the*, new form of the, 144; Engineers, Institution of, Sir Andrew Duncan elected an Honorary Member of the; Dr. A. P. M. Fleming awarded the Faraday medal, 174; Circuits, Making and Breaking, A. M. Cassie (*Review*), 370; Contacts, G. Windred (*Review*), 370; Music, Dr. W. Wilson, 449; Cables, buried, Protection of, R. P. Ashbaugh, 572; Engineers, Institution of, awards of premiums of the, 606
Electricity: in Agriculture and Horticulture, Utilization of, 62; in Agriculture, H. W. Grimmitt, 93; in Thunderclouds, Distribution of, Sir George Simpson and G. D. Robertson, 715
Electrodynamics: Prof. L. Paget, Prof. N. I. Adams, Jr. (*Review*), 398; Theory of, Prof. S. Chapman (*Review*), 398
Electrolytic Condensers: their Properties, Design, and Practical Uses, P. R. Coursey. Second edition. (*Review*), 74
Electron Diffraction, *N* Pattern of, A New Method of Obtaining the, S. Yamaguchi, 296
Electronic Engineering, Part 1, 741
Electrons, Polarization of, K. Kikuchi, 151
Elektrische Höchstspannungen, Dr. A. Bouwers (*Review*), 11
Elmswell, East Yorkshire, Excavations at, 1938, 243
Empire: Democratise the, a Policy for Colonial Change, Prof. W. M. Macmillan (*Review*), 591
Empirical Knowledge, The Foundations of, A. J. Ayer; Prof. H. Dingle (*Review*), 286
Empiricism in Metaphysics, Very Rev. Dean W. R. Matthews (*Review*), 309
Emulsions, Stability of, A. King and G. W. Wrzeszinski, 211
Engineering: Courses for Students in H.M. Forces, 143; in Warfare, appointment of an Advisory Committee on, 538; Economy and Æsthetics, 773
Engineers and Reconstructions, Viscount Falmouth, 113
Engineers': Achievements under Aerial Bombardment, Lord Lytton, 448; Year-Book of Formulæ, Rules, Tables, Data and Memoranda for 1941, revised under the direction of L. St. L. Pendred (*Review*), 790
Enzymes, X-rays and, W. M. Dale, 271
Eskimo Material Culture, 670
Europe: Collaboration in, 1; Continental, Mineral Resources of, Dr. W. J. Arkell, 404; under Hitler: in Prospect and in Practice (*Review*), 755
Evacuation, Sociological Aspects of, 272
Excavations at Elmswell, East Yorkshire, 1938, 243
Explosives, Prof. G. I. Finch, 501
Eye, Dark-adapted, Sensitivity of the, during a prolonged Period of Observation, Dr. B. Semeonoff, 454

Factory: Canteens, 264; Lighting in War Time, C. J. Misselbrook, 478
Farm Animals: Fertility, Growth and Breeding of, Dr. H. P. Donald (*Review*), 430; Their Breeding, Growth and Inheritance, Dr. J. Hammond (*Review*), 430; Feeding, the Principles and Practice of, E. T. Halnan and F. H. Garner (*Review*), 587
Farm and Forest, impending publication of, 477
Farmer, A Writer Turns, Sir John Russell (*Review*), 340
Farming: The New, Continuous Cropping by the Wibberley System, T. Wibberley (*Review*), 760
Fatigue Following Highly Skilled Work, Prof. F. C. Bartlett (Ferrier Lecture), 717
Fats, Melting Range of, K. A. Williams, 578
Federal: Government is, What, K. C. Wheare (*Review*), 461; Tracts, Nos. 1 to 7 (*Review*), 461; Union: and the Colonies, Lord Lugard (*Review*), 461; The Philosophy of, Prof. C. E. M. Joad (*Review*), 461
Federation; and its Implications, R. Brightman (*Review*), 461; Economic Aspects of, Prof. L. Robbins (*Review*), 461
Felling, the Effect of, on the Incidence of Forest Insect Pests, Dr. A. E. Cameron, 507
Fens, Drainage of the, W. E. Doran, 781
Finance and the War, Prof. F. Soddy, 449
Fisheries of Bengal, Dr. R. Naidu, 604
Fisher's, Mr., Autobiography, F. S. Marvin (*Review*), 523
Fishes: Migratory, Dams and the Problem of, 485; Sense of Hearing in, Dr. C. B. Williams, 543; M. Graham, 779
Fittig and Ullmann Reactions, Free Aryl Radicals in the, Dr. W. S. Rapson and R. G. Shuttleworth, 675
Flame Gases, Temperature and Latent Energy in, Prof. W. T. David, 89
Flax Crop, Stem-break, Browning and Seedling Blight in the, Prevention of, A. E. Muskett and J. Colhoun, 176
Flight: without Power: the Art of Gliding and Soaring, L. B. Barringer (*Review*), 38; Refuelling, Sir Alan Cobham, 172
Flint Flakes of the Crag Sea Floor, S. H. Warren, 60
Flora: of Town Ruins: of South Albania, A. H. G. Alston and N. Y. Sandwith, 82; and Fauna of the Inner and Outer Hebrides, Prof. J. W. Heslop Harrison, 134
Flour: National, Specifications for, 665; White, Deficiency of, in Riboflavin, Dr. G. Fraenkel and M. Blewett, 716
Fly, Seasonal Rhythm of a, Dr. Ll. Lloyd, 811
Flying Services, Preliminary Training for the, 84
Food in War-time, Lord Horder, 294; distribution in War-time, 335; Growing, Storing and Cooking, Penguin Book of, F. W. P. Carter, 706; the Deciding Factor, F. Wokes, 706
Forage Grasses, New Winter, W. Davis, 54
Foreign Periodicals in War-time, 773
Forest Administration, Colonial, late Prof. R. S. Troup (*Review*), 491
Forestry: Private, Economics of, Prof. R. W. Marquis; Prof. E. P. Stebbing (*Review*), 40; in Africa, 63; Administration, Prof. H. G. Champion (*Review*), 491; in Baluchistan, S. H. Howard, 363; Private Estates and, Major C. P. Ackers, 605
Fossils, Variation in, Prof. H. H. Swinnerton, 121
Fowl: Leukosis, Inactivation of the Causative Agent of, by X-Rays, Prof. L. Doljanski, Dr. G. Goldhaber and Dr. M. Pikovski, 481; Polydactyly in the, D. C. Warren, 748
Freedom: The Contempt of, the Russian Experiment and After (*Review*), 97
Frog's Egg, Developing, Field Properties of the, H. D. Burr, 780
Frost Resistance in Plants, Siminovitch and Levitt, 611
Fruit Planting, Fertility rules in, 236
Fuel Research Board, Report of the, for the Year ended 31st March, 1939, 33
Fungal Genera, Nomenclature of, E. M. Wakefield, 360
Fungi: The Advance of the, E. C. Large (*Review*), 279; Larger, in the Tropics, Occurrence of, E. J. H. Corner, 450.
Fusarium avenaceum, Biotin and the Growth of, W. J. Robbins, 780

Galactic Absorption, Uniform, Limits of, G. Alter, 810
Galaxy, Diffuse Radiation in the, Henyey and Greenstein, 613
Garden: Vegetables, Some Seasonal Pests of, G. F. Wilson, 210; Science, Dr. J. Grainger. Cheaper edition (*Review*), 312; Hygiene of the, D. E. Green, 742
Gardeners' Chronicle, Centenary of the, 144
Gas-gangrene Toxins, Nomenclature of, M. Llewellyn Smith, 87
Gases: Liquefaction of, Prof. H. W. Melville (*Review*), 464; The Separation of, Dr. M. Ruhemann (*Review*), 464

Generals and Generalship, Genl. Sir Archibald Wavell (Lees Knowles lectures), 293
Genetical Calculations, I. M. H. Etherington, 578
Genetics, Seventh International Congress of, Proceedings of the, 354
Genève, La Société de Physique et d'Histoire Naturelle de, Prof. F. E. Weiss, 566
Geography, Towards a New, W. A. Gauld, 546
Geological Society, awards of the, 145; 171
Geology: and Early Man, H. B. S. Cooke, Prof. C. van Riet Lowe and L. H. Wells, 45; T. T. Paterson, 49; Glacial, The Birth of, Dr. W. J. McCallien, 316; and the Community, 461; of Coal, O. Stutzer, translated and revised by the late Dr. A. C. Noé; Dr. M. Macgregor (*Review*), 521; Introduction to, General Geology, Dr. E. B. Bailey; Palæontology, Dr. J. Weir (*Review*), 556; Principles and Processes, Prof. W. H. Emmons, Prof. G. A. Thiel, Prof. C. R. Stauffer and Prof. I. S. Allison. Second edition (*Review*), 556; Influence of, on the Health of Grazing Animals, Dr. G. Dunlop and Dr. W. J. McCallien, 615; Structural, Outlines of, Dr. E. S. Hills (*Review*), 625
German: Chemical and Technical, Advanced Readings in, Selected and Edited by Prof. J. T. Fotos and Prof. R. N. Shreve (*Review*), 625; Aircraft Design, 773
Germany's 'New Order', D. Wilson (*Review*), 755

Gippsland, Victoria, Oil Search and Occurrence in, Sir Edmund Teale, 31
Glaisher's Table of Powers, Prof. E. H. Neville, 241
Glasgow, Health of, Dr. A. S. M. Macgregor, 639
Glasgow University, Air Raid Damage to, 411
Glass Manufacturers' Federation, Establishment of a Defence Advisory Panel, 673
Glycogen Storage in the Fasting Rat, Influence of Œstrogens and Androgens on, M. Griffiths, Dr. H. P. Marks and Dr. F. G. Young, 359
Goethe medal for Art and Science, Award of the, to Prof. M. Nonne, 775
Goldsmiths' College, Air raid damage to, 112
Government Changes, 570
Grand Coulee Dam, The, 412
Gravity: Anomalies and the Figure of the Earth, B. L. Gulatee, 273; Ellipticity Term in, Dr. H. Jeffreys, 613
Grazing Animals, Health of, Influence of Geology on the, Dr. G. Dunlop and Dr. W. J. McCallien, 615
Greece and Great Britain, Cultural Treaty between, 82
Grew, Nehemiah, Tercentenary of, (1641–1712), Dr. Agnes Arber, 630
Guatemala, Health Conditions in, Genl. J. Ubico, 24
Gypsy-Lore, 603

Hair, Human, Composition of, R. C. Clay, K. Cook and J. I. Routh, 30
Haisla, British Columbia, Social Organization of the, R. L. Olson, 90
Haricot Beans, G. St. Clair Feilden, 507
Harvard University: Farlow Herbarium, Dr. F. Verdoorn appointed a research associate of the, 265; conferment of an honorary doctorate on Viscount Halifax, 800
Head Injuries, Psychological Terms used in, 538
Heat and Temperature Measurement, A Manual of, R. L. Weber (*Review*), 791
Heavy Ionization Particles Detected on Photographic Plates Exposed to Cosmic Rays, Origin and Nature of, Dr. D. M. Bose and Miss Biva Chowdhry, 240
Hebe, Veronica and Pygmœa, Cytology and Taxonomy of, Dr. O. Frankel, 117
Hebrides, Inner and Outer, Flora and Fauna of the, Prof. J. W. Heslop Harrison, 134
Hemp Drugs, The Actions and Uses of, Prof. A. D. Macdonald, 167
Heterosis, E. S. J. Hatcher, 483
Heterotrophic Organisms, Carbon Dioxide Assimilation in, Dr. H. A. Krebs, 560
Histology and Embryology, Practical, Dr. Nellie B. Eales (*Review*), 495
'Historical Materialism', Dr. C. F. Powell, 119
History, The Golden Ages of, J. McCabe (*Review*), 8
Hitler's 'New Order' in Europe, P. Einzig (*Review*), 755
Hollerith Computing Machines (*Review*), 131
Homœopathy, Principles and Practice of, An Introduction to the, Dr. C. E. Wheeler. Second edition (*Review*), 73
Honours List, New Year, 52
Hormones: Capable of Increasing Liver Fat, O. Riddle and D. F. Opdyke, 748; Adrenal Cortical, Correlation between Sex-, Thyroid- and, Dr. W. Korenchevsky and K. Hall, 777
Horrocks, Jeremiah, Tercentenary of, 23
Hot-Tinning, C. E. Horner, 484
Human: Values, Psychology and, A. W. P. Wolters (*Review*), 41; Skull, Early Growth of the, Dr. C. B. Davenport, 90; Truths, Our, late Dr. F. C. S. Schiller (*Review*), 102
Humanism and Life (*Review*), 102
Humanities, Suicide of the, Dr. C. H. Waddington (*Review*), 621
Humus: and the Farmer, G. V. Jacks, 354; from Habitation Wastes, Prof. R. H. Stoughton; Lt.-Col. F. C. Temple, 457
Hungarian Throwing-Sticks, B. Garda, 330
Hydrocarbon Salts, Formation of Ions from Compounds with Conjugated Double Bonds, Dr. J. Weiss, 512
Hydrocarbons: Slow Combustion of, Surface Effect in, Dr. R. G. W. Norrish and J. D. Reagh, 331; Volumetric and Phase Behaviour of, Prof. B. H. Sage and Prof. W. N. Lacey (*Review*), 372
Hydrogen Bond in Protein Structure, A Possible New Approach to the Study of the, Dr. A. E. Alexander and Prof. E. K. Rideal, 541
Hydroid, A Giant, S. M. Manton, 121
Hydroxyl, Replacement of, by Halogen, The Walden Inversion in the, Dr. E. D. Hughes, Prof. C. K. Ingold and I. C. Whitfield, 206
Hymenoptera, Genitalia of, Dr. R. E. Snodgrass, 611
Hypochlorite Aerosols, Stability of, Hydration of Carbon Dioxide and the, P. V. Youle, 59
Hyrax, Placentation of, G. B. Wislocki and O. P. van der Westhuysen, 29

Iceland: Health of, Dr. V. Jonsson, 413; Hot Springs and Geysers of, Dr. L. Hawkes (*Review*), 788; On Thermal Activity in, and Geyser Action, T. Thorkelsson (*Review*), 788
Ichthyosaurian Fossil, An, 264
Imperial: Cancer Research Fund, bequest to the, by Sir Robert Hadfield, Bart., 237; College of Science, Foundation of a scholarship in the, by the Scientific Instrument Manufacturers Association, 639
Index Londinensis: Prof. J. R. Matthews (*Review*), 397; to Illustrations of Flowering Plants, Ferns and Fern Allies, Supplement for the Years 1921–35. 2 Vols. (*Review*), 397
India: Issues and Parties in, 353; at War, Sir George Dunbar, 412; Meteorology in, 539; Agricultural Meteorology in, 571; Engineering Construction in, 672
Indian Society of Genetics and Plant Breeding, election of officers, 573
Industrial: Health Education Society, Closing down of the, 114; Progress, Whither and Why, C. H. H. Franklin, 801
Infectious Disease, Biological Aspects of, Dr. F. M. Burnet (*Review*), 74
Infestation of Manufactured Food by Insects, Dr. D. N. Roy, 746; Prof. J. W. Munro, 808
Inks, Printing: The Genesis of, Dr. E. F. Armstrong (*Review*), 589; their Chemistry and Technology, late Carleton Ellis (*Review*), 589
Inorganic Substances, Metabolism of, Prof. J. H. Gaddum (*Review*), 431

Insect Cuticle: The Protein of, A. R. H. Trim, 115; Permeability of, Dr. V. B. Wigglesworth, 116; as an Asymmetrical Membrane, H. Hurst, 388; Cuticles, Relation between Colour and Permeability of, H. Kalmus, 455
Instinctive Behaviour, Biological Adaptedness and Specialization of, Dr. E. S. Russell, 729
Interface, The Oil/Water, Dr. J. H. Schulman, 197
Internal Combustion Engines, Recent Developments in, Prof. S. J. Davies, 487
International: Co-operation, A Basis of, 245; Cultural Relationships, 277; Democracy of Science during War and Reconstruction, Dr. D. L. Fox, 640
Interstellar Space, Selective Absorption of Light in, Dr. A. Hunter, 152
Interview, The Psychology of the, R. C. Oldfield (*Review*), 693
Interviewing, Essentials of, (*Review*), 693
Intestinal Absorption, Radioactive Indicators, Enteric Coatings and, Prof. K. Lark-Horovitz and Dr. Herta R. Leng, 580
Invertebrates: The, Protozoa through Ctenophora, Libbie Henrietta Hyman (*Review*), 160
Iodic Acid, Crystal Structure of, M. T. Rogers and L. Helmholz, 612
Iodine, Vapour Density of, G. K. Rollefson and Perlman, 810
Ionic Clouds, Transient, Origin of, Prof. P. M. S. Blackett and A. C. B. Lovell, 680
Ions from Compounds with Conjugated Double Bonds: Formation of Hydrocarbon Salts, Dr. J. Weiss, 512
Iraq, Electrical Developments in, 204
Iris pseudacorus, Pigments of, W. F. O'Connor and Dr. P. J. Drumm, 58
Iron and Steel Institute, award of the Bessemer gold medal to Dr. T. Swinden, 410
Island: Steps to an, Seton Gordon (*Review*), 524; The Way to an, R. M. Lockley (*Review*), 524
'Isoflex', a Plastic for Thermal Insulation, 508
Isotope Exchange in Organic Compounds, D. J. G. Ives and R. H. Kerlogue, 60

Japan Institute for the Science of Labour, Annual Report for 1939, 803
Jehanne La Pucelle, A Medico-Psychological Revision of the Story of, Dr. H. P. Bayon, 23
Jewish Question, The, J. Parkes, 801
Judd, Katherine Berkan, prize, award of the, to Dr. E. L. Kennaway and Prof. J. W. Cook, 573

Kent's Cavern, Early Exploration of, 202; H. V. Thompson; A. H. Ogilvie, 455
Keratin, Alpha-, and Alpha-Myosin, Nature of the Intra-molecular Fold in, Dr. W. T. Astbury and Dr. Florence O. Bell, 696
Kew: The Royal Botanic Gardens, Centenary of a Government Institution. Prof. F. O. Bower, 400; Sir Arthur Hill, 402
"Kill Statistics" from California, D. H. Fry, jun., 672
Kinetic Friction Coefficient, Prof. S. Russ, 712
Knowledge: Theory of (*Review*), 493; The Analysis of, Prof. L. Wood (*Review*), 493
Königsberg University, Award of the Copernicus prize to Prof. O. Hahn, 775
Kromnek (Spotted Wilt) Disease of Tomatoes, Control of the, Dr. Enid S. Moore, 480
Kryptogamen, Sammeln und Präparieren der niederen, Hilfsbuch für das, Prof. G. Lindau. Zweite Auflage von Prof. O. C. Schmidt (*Review*), 11
Kungl.-Svenska Vetenskapsakademien, Dr. B. Hildebrand (*Review*), 495

Labour and National Service, Ministry of; appointment of Sir William Beveridge as an under-secretary to the, 114
Lacertæ, 12, Photo-electric Observations of, H. E. Green, 579
Lachish II (Tell-Ed-Duweir): The Fosse Temple, Olga Tufnell, C. H. Inge and L. Harding (*Review*), 71
Lactation, Physiological Aspects of, Dr. S. J. Folley, 120
Lake Deposits, The Study of, B. M. Jenkin, C. H. Mortimer and W. Pennington, 496
Lakeland, English, Doreen Wallace (*Review*), 372
Larch Wood, The ξ-Galactan of, Prof. E. L. Hirst, Dr. J. K. N. Jones and W. G. Campbell, 25
Larval Siricidæ (Hymenoptera), Symbiosis in, E. A. Parkin, 329
Laue Photographs, The Extra Spots in, Prof. G. E. M. Jauncey, 146
Leeds: University, Dr. F. C. Happold elected Reader in Biochemistry in, 387; City Museum, Air raid damage to the, 411
Leguminous Root Nodules, Respiration of, Dr. G. F. Asprey and Dr. G. Bond, 675
Lemon Seedlings, Nitrogen/Phosphorus Relations in, J. W. Pont, 781
Leopold Caroline, Academy of Natural Science at Halle, Prof. J. Seiler elected a member of the, 174
Lescaux (Montignac, Dordogne), A Remarkable Painted Cave on the Estate of, Prof. the Abbé H. Breuil, 12
Leyden: the University of, Contributions to Biology and Medicine, Prof. F. J. Cole, 161; Contributions to Physics and Chemistry, Dr. L. C. Jackson, 163
Librarians, Reservation of, J. Hawnt, 677
Lice: Control of, Prof. P. A. Buxton, 85; Incidence of, Dr. K. Mellanby, 611
Liebig Centenary, A, 227
Light: in Interstellar Space, Selective Absorption of, Dr. A. Hunter, 152; in Gases under Electrical Discharge, An Effect of, Prof. S. S. Joshi and G. S. Deshmukh, 806
Lightning and Spark Discharges, The, C. E. R. Bruce, 805
Lily Mosaic, D. E. Green and Dr. M. A. H. Tincker, 611
Linnean Society of London: Award of the gold medal of the, to Prof. A. G. Tansley, 669; election of officers, 673
Liquids: in small Capillaries, Properties of, L. H. Cohan and G. E. Meyer, 61; Dielectric Constant of, Effect of Flow on the, Prof. S. P. Prasad, B. N. Singh and B. D. Singh, 712
Lithium, Stellar, Dr. A. McKellar, 810
Liverpool University: Air raid damage to, 53, 448; Bequest to, by Mrs. Mary Harmood Hamilton, 237
Livestock, The Feeding of, Dr. C. Crowther (*Review*), 587
Lizards, Fossil, from Utah, C. W. Gilmore, 644
L.M.S. Railway, award of the Herbert Jackson prize of the, to S. C. Britton, 387
Locust officer in Northern Rhodesia, A. P. G. Michelmore appointed, 172
London: The Fire of, 20; University, the certificate of proficiency in Natural History, 54; Museum, Air raid damage to the, 323; University: H. Claughton appointed acting principal of; Dr. J. H. Gray appointed professor of anatomy at St. Mary's Hospital Medical School; title of professor conferred on Dr. E. C. Sprawson and that of reader on Dr. T. Esterman and A. C. Stevenson; establishment of the William Gilles fellowship in science by the Clothworkers Company, 355; Certificate in Natural History, 450; conferment on K. C. Richardson of the title of reader, 540; County Council, Vital Statistics of the, 572; Mathematical Society, award of the De Morgan medal of the, to Prof. L. J. Mordell, 708; University, Prof. F. Horton re-elected vice-chancellor; Dr. R. J. W. Le Fèvre appointed reader in chemistry at University College; conferment of doctorates, 804
Louvain University, Losses to, by hostilities, 673
Lubricant Films, Desorption or 'Surface Melting' of, Dr. D. Tabor, 609
Lubricated Surfaces, The Static Friction of, Fogg and Hunwicks, 324
Lubrication: Technique, 'Prelubrication' for, 324; Long-Chain Polar Compounds in, O. Beeck, J. W. Givens and A. E. Smith, 613
Lundy: Birds of, Seton Gordon (*Review*), 248; Isle of Puffins, R. Perry (*Review*), 248

Magnesium, Manufacture of, 638
Magnetism and Very Low Temperatures, H. B. G. Casimir (*Review*), 728
Magnetization of Matter by Light, Prof. F. Ehrenhaft and Dr. L. Banet, 297
Malaria in War: Dr. V. B. Wigglesworth, 436; Brig.-Genl. G. E. Smith, 576
Malaya: Trees of, Sir Arthur Hill (*Review*), 6; Wayside Trees of, E. J. H. Corner. Vol. 1 (*Review*), 6; Rubber Research Institute of, Sir Geoffrey Evans, 15; Timber Utilization in, H. E. Desch and A. V. Thomas, 572
Malignant Growths, Periodicity in, Dr. P. A. Gorer (*Review*), 68
Mammalian Organism, Evolution of Function in the, Sir Joseph Barcroft, 762
Mammals: British, Recent additions to, 83; and Man, C. Matheson, 236
Man: Early, Geology and, H. B. S. Cooke, Prof. C. van Riet Lowe and L. H. Wells, 45; T. T. Paterson, 49; power, Utilization of, 65; Microbe and Malady, Dr. J. Drew (*Review*), 99; on his Nature, Sir Charles Sherrington (Gifford Lectures) (*Review*), 127; The Nature of, Prof. A. D. Ritchie (*Review*), 127; The Uniqueness of, Dr J. Huxley (*Review*), 247; of Science as Aristocrat', 'The: Lt.-Col. J. T. C. Moore-Brabazon, 544; Sir Richard Paget, Bt., 545; H. G. Wells; R. W. Paul, 610; correction to communication on p. 465, 639; of Science as Aristocrat', 'The, R. A. Jones, 677; -Power: Economic Policy and, 185; Resources and, Scientific Utilization of, 365; G. H. Ince appointed director-general of, 740
Manchester: Literary and Philosophical Society, Air raid damage to the, 352; School of Pure Mathematics; award of the De Morgan medal to Prof. L. J. Mordell and of the Adams prize to Dr. H. Davenport, 740
Maple, Hybrids of the, O. M. Freeman, 748
Marine: Animals, Living, Weighing: A. G. Lowndes, 298; Dr. G. P. Bidder, 328; Biological Association's Laboratory, Air raid damage to the, 411; Engineering Institution, An Early, Eng.-Capt. E. C. Smith, 539; Animal Oils, Prof. T. P. Hilditch, 548; Biological Association of the United Kingdom, re-election of Dr. G. P. Bidder as president of the, 775
Mars: The Surface of, Dr. E. C. Slipher, 30; water on, 646
Martensite on Wire Ropes, Formation of, E. M. Trent, 645
Materia Medica Cabinets in Cambridge, Three Early, E. S. Peck, 423
Mathematician's Apology, A, Prof. G. H. Hardy (*Review*), 3
Mathematics: Living, a First Year College Course, Prof. R. S. Underwood and Prof. F. W. Sparks (*Review*), 73
Mauritius and Rodriguez, The Grasses of, C. E. Hubbard and Dr. R. E. Vaughan (*Review*), 11
Mechanical Engineers, Institution of: W. A. Stanier elected president of the, 262; awards for 1941 of the, 295
Medical: Dictionary, A Pocket, L. Oakes, assisted by T. B. Davie. Fourth edition (*Review*), 10; Planning Commission, A, 53
Medicinal: Formulæ, War-time, 706; Herbs, 774
Mental Health in War-time, Sir Walter Langdon-Brown (Chadwick Lecture), 193
Merseyside Naturalists' Association, election of officers, 294
Mesotrons in a Large Wilson Chamber, Experiments with, R. P. Shutt and T. H. Johnson, 750
Metal Films, Catalytic Activity and Structure of, O. Beeck, A. E. Smith and A. Wheeler, 646.
Metallic Triazine Complexes, F. P. Dwyer; F. P. Dwyer and D. P. Mellor, 612
Metals, Institute of, award of the medal of the, to Dr. C. H. Desch, 670
Metaphysics: An Essay on, Prof. R. G. Collingwood (*Review*), 7; Rediscovered, Miss B. M. Baldwin (*Review*), 7
Meteor Observations in India during 1940, M. A. R. Khan, 742
Meteorite, The Shallowater, W. F. Foshag, 484
Meteorites, Origin of, Prof. F. A. Paneth (Halley Lecture), 242
Methane: as a Fuel (*Review*), 281; its Production and Utilization, Dr. J. P. Lawrie (*Review*), 281
Mica in Tanganyika, G. J. Williams and A. F. Skerl, 211
Microentomology, recent issues, 237
Microfilm, Reading machine for, 84
Micro-organisms, Nitrogen-fixing and Cellulose-decomposing, Association between, H. L. Jensen and R. J. Swaby, 147
Microscope: The, R. M. Allen (*Review*), 129; Cover-Slips, Thin Glass for, 803
Microscopy, Modern (*Review*), 129
Migration to and from the British Isles: Problems and Policies, E. S. Walshaw (*Review*), 553
Min Chia, Yunnan, Festivals of the, C. P. Fitzgerald, 213
Mineral: Resources of Continental Europe, Dr. W. J. Arkell, 404, 443; Metabolism, Dr. A. T. Shohl (*Review*), 431
Mineralogical Society of America, Dr. L. J. Spencer awarded the Roebling medal of the, 295
Minerals in Sedimentary Rocks, Stability of, Prof. P. G. H. Boswell, 734
Mining and Metallurgy, Institution of: E. H. Clifford elected president of the, 171; awards made to C. R. Julian, J. Spalding, T. W. Parker, J. E. Denyer and K. C. G. Heath; H. K. Picard elected an honorary member of the, 573
Molecular Spectra and Molecular Structure. I: Diatomic Molecules, Prof. G. Herzberg. Translated by Prof. J. W. T. Spinks; Prof. C. K. Ingold (*Review*), 36
Molecules: Aggregates of, Structure of Molecules and, Prof. J. G. Kirkwood and others, 648; Structure of, and Aggregates of Molecules, Prof. J. G. Kirkwood and others, 648
Molybdenum and Tungsten in the Caucasus, 264
Moon: Rocket Flight to the, J. W. Campbell, 235; Earth and, Figures of the, Dr. H. Jeffreys, 484
Moss in War-time Medical Dressings, 21
Motor-: Vehicle Industry in Great Britain, 386; Car Engines, Research on (*Review*), 691
Mucors, Spore Discharge in the, C. T. Ingold, 150
Multilayers, Structure of, G. Knott, Dr. J. H. Schulman and A. F. Wells, 271
Mummification in America: Dr. A. Hrdlička, 413; 707
Municipal Trading: a Study in Public Administration, Dr. H. Finer (*Review*), 489
Muscina stabulans Fallen, Flight of a Dipterous Fly, F. S. G. Hollick, 270
Museum Specimens, Mounting, in Plastic, 236
Mycology, A History of, J. G. Crowther (*Review*), 279
Myosin, Alpha-, Alpha-Keratin and, Nature of the Intramolecular Fold in, Dr. W. T. Astbury and Dr. Florence O. Bell, 696; Birefringence and Adenylpyrophosphate, Dr. J. Needham, Dr. Shih-Chang Shen, Dr. Dorothy M. Needham and Dr. A. S. C. Lawrence, 766

Naphthalene Crystals, Conical Refraction in, Sir C. V. Raman, V. S. Rajagopalan and T. M. K. Nedungadi, 268
National: Museum of Wales, temporary exhibition of Mammals and Man, 325; Expenditure, The Select Committee of, 585; Planning, Agricultural Land and, Dr. L. Dudley Stamp, 647; Central Library, The, 651
Nation's Resources, Co-ordination of the, 215
Natural Gas in Brantford Area, Ontario, J. F. Caley, 651
Nature, Dialectics of, F. Engels. Translated and edited by C. Dutt (*Review*), 187
NATURE and the War, 321
Nettles, Feeding Dried, to Livestock, W. King Wilson, 796
Neuroptera of the Nearctic Region, F. M. Carpenter, 644
New Guinea, Anthropological Observations in, 507
New York: State, Population Increase in, W. A. Anderson, 124; Academy of Sciences, Sir Arthur Keith elected an honorary member of the, 205

New Zealand : The Fauna of, H. B. Fell, 253 ; Dobsonfly, Avice Hamilton, 300 ; Metamorphism in, C. O. Hutton, 483 ; Forestry in, A. R. Entrican, 672 ; Crustal Structure of, K. E. Bullen, 685 ; Variability of Annual Rainfall in, C. J. Seelye, 714
Newts, Triploid, R. B. Griffiths, 578
Nicotiana, Trisomics in, T. H. Goodspeed and P. Avery, 612
Nicotinamide Cozymase and Tissue Metabolism, Dr. P. J. G. Mann and Dr. J. H. Quastel, 326
Nigeria, Ifé, Bronze Head from, H. J. Braunholtz, 270
Nigerian Forester, Discontinuance of the, 477
Night Sky in : February, 145 ; March, 265 ; April, 387 ; May, 509 ; June, 673 ; July, 804
Night Bomber, Defence against the, N. Pemberton-Billing (*Review*), 657
Nitrification by Chromates, Inhibition of, Dr. S. H. Jenkins and C. H. Hewitt, 239
Nitrites, Bacteriostatic Action of, Dr. H. L. A. Tarr, 417 ; (correction), 708
Nitrogen : Biological Fixation of, Dr. G. Bond (*Review*), 789 ; Fixation, Symbiotic, The Biochemistry of, Prof. P. W. Wilson (*Review*), 789
Nitroxyl Perchlorate, W. E. Gordon and J. W. T. Spinks, 151
Nodule Bacteria and their Hosts, H. K. Chen, Dr. H. Nicol and H. G. Thornton, 210
Norfolk Farm, The Story of a, H. Williamson (*Review*), 340
Nottingham, University College, Air-raid damage to, 773
N.S.W., A new Diesel-Engine driven Generating Station in, 386
Nuclear Structure, Laws of, derived from Nuclear Spins, Dr. S. Tolansky, 269
Number : The Language of Science, Prof. T. Dantzig. Second edition (*Review*), 9

Occupational Information and Guidance : Organization and Guidance, 234
Ocean Sediments, Radioactivity of, C. S. Piggot and W. D. Urry, 749
Œnothera cantabrigiana, B. M. Davies, 483
Oil : Search and Occurrence in Gippsland, Victoria, Sir Edmund Teale, 31 ; /Water Interface, The, Dr. J. H. Schulman, 197
Oleanolic and Related Acids, Position of the Carboxyl Group in, P. Bilham and Prof. G. A. R. Kon, 745
Opalinid Infusorians, Geographical Distribution of, M. M. Metcalf, 300
Orchid Seed, Germination of, under Sterile Conditions, D. G. Downie, 578
Orders, The Two (*Review*), 755
Organic Reactions, Exact Studies of, Dr. W. A. Waters (*Review*), 101
Osmium, Behaviour of Nitrogen and Hydrogen on, H. S. Taylor and Joris, 809
Ostwald's Chromatic Standards, Æsthetic Appeal of, Dr. J. B. Parry, 782
Ovarian Follicular Hormones (a correction), Prof. E. A. Doisy, 173
Overseas Students in Great Britain, Prof. B. Ifor Evans, 113
Oxford : and Cambridge Universities, An American Tribute to, 53 ; University, Bequest to, by Dr. J. Burtt Davy, 237 ; conferment of an honorary doctorate on Prof. J. B. Conant, 355 ; University, conferment of an honorary doctorate on President Roosevelt, 800
Oxygen, Heavy, O. R. Alexander and N. F. Hall, 361

Painted Cave, A Remarkable, on the Estate of Lescaux (Montignac, Dordogne), Prof. the Abbé H. Breuil, 12
Paintings, Examination of, Application of Modern Physics in the, Dr. H. J. Plenderleith, 165
Palæochemistry of the Ocean, Prof. E. J. Conway, 480
Palestine : Early, Cult and Crafts in, Prof. J. L. Myres (*Review*), 71 ; Jewish Population of, 413
'Pancake' Ice in the Pennines, Capt. N. E. Odell, 545
Paper from Straw, Dr. Julius Grant, 142
Paralysis Produced in White Rats by a Rachitogenic Diet, Dr. H. A. Shapiro, 362
Paranthropus Child, Mandible of a Young, Dr. R. Broom, 607
Parliamentary and Scientific Committee, Earl of Dudley elected president of the, 174
Pavlov Manuscript, A New, 236
Peace : The War for, L. Woolf (*Review*), 130 ; by Federation ?, Sir William Beveridge (*Review*), 461; ?, Lasting, What are the Hopes of, D. Hall, 476 ; and War, The Moral Paradox of, Prof. J. C. Flugel (Conway memorial lecture) (*Review*), 761
Peat, Studies in, Prof. J. Reilly and J. R. O'Donoghue, part 10, 708
Peirce : The Philosophy of, Selected Writings, Edited by Dr. J. Buchler (*Review*), 220
Pentatonic Scale, Origin of the, E. C. Curwen, 90
Periodic Motion, Early Work on, A. E. Bell, 78
Pest Control, Materials for, 262
Petroleum in Australia, Search for, H. B. Milner, 13
Pharmaceutical : Students and Military Service, 232 ; Society : Centenary of the, 471 ; work of the, Sir John Anderson, 506 ; award of the Hanbury medal to Dr. H. King, 637
Pharmacology : Prof. J. H. Gaddum (*Review*), 593 ; with Grace, Prof. J. H. Burn (*Review*), 593
Pharmacopœia, The British, in War-time, 64
Phosphoryl Bromide, C. R. Johnson and L. G. Nunn, 750
Photismi de Lumine of Maurolycus : The, a Chapter in late Medieval Optics, translated by H. Crew (*Review*), 525
Photons, Crystals and, Sir C. V. Raman, 485
Photosynthesis : Prof. E. C. C. Baly (*Review*), 97 ; by Plants and by Chemists, Dr. W. O. James (*Review*), 97 ; S. Ruben, M. D. Kamen, W. Z. Hassid and L. H. Perry, 420
Physical : Society, presentation of the Duddell medal to Prof. E. O. Lawrence, 22 ; Science in Art and Industry, Dr. E. G. Richardson (*Review*), 67; Society, Guthrie Lecture of the, Prof. E. N. da C. Andrade, 410
Physicist ?, What is a, 617
Physics : in Modern Life, F. I. G. Rawlins (*Review*), 67 ; Taste in, A Question of, Prof. W. H. McCrea (*Review*), 100 ; Modern, Application of, in the Examination of Paintings, Dr. H. J. Plenderleith, 165 ; Teaching, Dr. W. H. George (*Review*), 280 ; The Demonstration Laboratory of, at the University of Chicago, Prof. H. B. Lemon and Fitz-Hugh Marshall (*Review*), 280 ; New Instruments in, K. K. Darrow, 539 ; General, W. L. Whiteley (*Review*), 624 ; Intermediate Practical, T. M. Yarwood (*Review*), 624 ; School (*Review*), 624 ; Institute of, Inaugural Meeting of the Industrial Radiology Group, 706 ; Experimental College, a Laboratory Manual, Prof. M. W. White. Second edition (*Review*), 728 ; University, part 2 : Heat, Dr. F. C. Champion (*Review*), 728; Institute of, election of officers, 775
Pits in the Ears, Inheritance of, H. W. Edwards and C. E. Keeler, 679
Pituitary Hormones, Multiplicity of, Dr. H. Heller, 178
Place-Names in the United States, Dr. J. P. Harrington, 604
Plagiophyres in an Intrusion at Downpatrick, E. M. Patterson, 778
Planets : The Physical Condition of the, Sir James Jeans, 526, 747 ; The Physical Condition of the, J. Phelps, 746
Plankton : as a Source of Food, Prof. A. C. Hardy, 695, 705 ; of the Australian Coastal Waters of N.S.W., Part 1, Prof. W. J. Dakin, 705 ; as a Source of Food", Dr. E. Walker, 808
Planning : Reconstruction and, 653 ; in Great Britain, D. E. Gibson and others, 684
Plant : Cells, Water Relations of : T. Bennet-Clark and D. Bexon, 179 ; Virus Diseases, Control of, by Cultural Methods, I. W. Selman, 181 ; Microtechnique,

D. A. Johansen (*Review*), 222 ; Diseases, Minor, W. C. Moore, 330 ; Growth Substances in Practice, Application of, Dr. M. A. H. Tincker, 439 ; Cell Walls, 'Crossed Fibrillar' Structure of, Dr. R. D. Preston, 710 ; Tissues, Relative Position of Cell Walls in Developing, E. W. Sinnott and R. Bloch, 749

Plants : Mineral Nutrition of, 292 ; Useful and Ornamental, 686

Pleistocene, Divisions of the, T. T. Paterson, 781

Plotz, Ella Sachs, Foundation, Seventeenth Annual Report of the, 325

Polygenic Characters, Pseudo-dominance in, Dr. T. M. Olbrycht, 57

Pomatoceros, Sabella and Amphitrite, Joan G. Thomas (*Review*), 73

Pope Collection of Alchemical Paintings and Engravings, The, Prof. J. Read, 243

Poppy, Food from the, Dr. R. Melville, 412

Population : Increase in New York State, W. A. Anderson, 124 ; Problems and Educational Policy, 305

Pork, Rancidity of, and its Prevention, W. H. Cook and W. H. White, 644

Portulaca grandiflora, Effect of Temperature on the Mutation Rate of an Unstable Gene in, Dr. G. H. Beale and Dr. A. C. Fabergé, 356

Post-Glacial Conditions in England, Early, R. G. Carruthers and W. Anderson, 28 ; -War Reconstruction, Science and, President Roosevelt, 351

Potassium, Cellular, Physiological Origins of, Prof. E. J. Conway, 574

Potato : as Food, The, 103 ; Biology of the, Dr. R. Salaman, 103 ; Chemical Constitution of the, Dr. L. H. Lampitt and N. Goldenberg, 103 ; Nutrition Value of the, Dr. Harriette Chick, 103 ; Tubers, Blackening of, on Boiling, Ursula M. Robison, 777

Poultry : Diseases of, their Ætiology, Diagnosis, Treatment and Control, E. Gray (*Review*), 312

Power and Combustion, Prof. A. C. G. Egerton (Thomas Hawksley lecture), 122 ; -Tables, Prof. E. C. Titchmarsh (*Review*), 219

Prayer, National Day of, 322

Prehistoric Communities of the British Isles, Prof. V. Gordon Childe ; Mrs. J. J. Hawkes (*Review*), 337

Propaganda in Europe, 755

Propane, Thermodynamic Properties of, J. H. Burgoyne, 579

Proper Motions, Systematic Corrections to, Dr. W. M. Smart, 680

Protein : Films, True Surface Densities of, A. Norris, 358; Structure, The Hydrogen Bond in, a Possible New Approach to the Study of, Dr. A. E. Alexander and Prof. E. K. Rideal, 541 ; Structure, Dr. D. M. Wrinch, 646

Proteins, etc., Electrophoretic Study of Complexes between, D. A. MacInnes and L. G. Longworth, 781

Proton, Hydration of the, Heat of, Dr. E. C. Baughan, 30

Protons, Ionization Maximum for, Dr. N. Feather, 510

Psychical Research, Recent Trends in, Dr. E. J. Dingwall (*Review*), 217

Psychologie, Nouveau traité de, Prof. G. Dumas, Tome 6 : Les fonctions systématisées de la vie affective et de la vie active (*Review*), 41

Psychology : Psychotherapy and Evangelicalism, Prof. J. G. McKenzie (*Review*), 10 ; and Human Values, A. W. P. Wolters (*Review*), 41 ; in Education, Dr. H. Sorenson (*Review*), 555 ; in War-time, The Uses of, Dr. C. S. Myers, 564 ; Industrial, for Foremen, Dr. C. S. Myers (*Review*), 592

Ptinid Beetles of Economic Importance, H. E. Hinton, 713

Pulmonary Tuberculosis, Folk-Lore of, Dr. J. D. Rolleston, 671

Quantitative Analysis, Prof. H. S. Booth and Prof. V. R. Damerell (*Review*), 525

Queensland, Vital Statistics in, 804

Qui s'accuse s'acquitte, Prof. F. Soddy (*Review*), 3

Rachitic Rats, Influence of Vitamin D upon the Incisor Teeth of, Prof. J. T. Irving, 608

Radiation Mutations in Mankind, Role of, Dr. H. J. Muller, 718

Radioactive : Indicators, Enteric Coatings and Intestinal Absorption, Prof. K. Lark-Horovitz and Dr. Herta R. Leng, 580 ; Copper and the Mechanism of Oligodynamic Action, D. Mazia and Dr. L. J. Mullins, 642

Radioactivité et transmutation des atomes, Dr. T. Kahan (*Review*), 761

Radiography : Application of, to the Electrical Industry, H. P. Rooksby and Miss K. L. Jackman, 183 ; Industrial, Conference on, 183

Radiological Examination of Light Alloy Castings used in Aircraft Construction, W. L. Harper, 183

Radio Programmes, Design of Wire Networks Carrying, A. E. Bachelet, 802

Radio Traffic Control in America, 450

Radiology, Industrial and Engineering : Photographic Materials Specially Adapted to the Needs of, Dr. L. Mullins, 184

Radii, Covalent, V. Schomaker and D. P. Stevenson, 579

R.A.F. Food Supplies, Dr. T. F. Macrae and Squadron-Leader Stamm appointed to watch over, 740

Railway : Network Principles, New, J. F. Pownall, 92 ; Rationalization, 92

Railways under War Conditions, Lord Stamp, 322

Rainbow Trout, Frontal Bones of the, Development of the, J. A. Moy-Thomas, 681

Rat, Parathyroid Glands and Lactation in the, Dr. S. J. Folley, 744

Rationalist Annual, 1941, 233

Ray Society, Annual Report of the, 742

Reception Areas, Conditions in, Report on, 272

Reconstruction : a Committee on, 53 ; Aspects of, I, 395 ; II, 425 ; and Planning, 653

Red Sea : Corals, Dr. C. Crossland, 644 ; Topography of the, 679

Reef Corals, Studies on, 360

Reflectors, Electro-formed, 803

Regionalism in administration, 619

Relativity : The Special Theory of, Prof. H. Dingle (*Review*), 100 ; in the Remotest Heavens, Sir Joseph Larmor, 175

Research, State Planning of, (*Review*), 97

Resins, Natural Phenolic, Constituents of, Prof. R. D. Haworth, 255

Resources and Man-Power, Scientific Utilization of, 365

Respirator, The, in an Emergency, 352

Rhamnose Derivatives from *Ulva lactuca*, Isolation of, Miss M. M. T. Plant and Miss E. D. Johnson, 390

Rheology of Plastic Materials : D. C. Broome and L. Bilmes, 176 ; a correction, 237

Riboflavin : in Black Pepper, G. E. Shaw and H. G. Hind, 209 ; Deficiency of White Flour in, Dr. G. Fraenkel and M. Blewett, 716

Rickets, Calcium and Cereals, 225

Road Accidents to Children, Increase of, 414

Rockefeller Institute, retirement of Prof. W. J. V. Osterhout, 111 ; Foundation, Work of the, in 1940, Dr. R. B. Fosdick, 811

Rocks, Thermal Conductivity of, F. Birch and H. Clark, 301

Root Cuttings, Regeneration of, Effect of X-Rays on the, Dr. W. Plant, 575

Ross's Goose, Breeding-place of, P. A. Taverner, 678

Rothamsted Field Experiments on the Growth of Wheat, Dr. R. D. Preston, 583

Royal : Academy, Science and Art at the, Dr. A. T. Hopwood, 599 ; Astronomical Society, Election of Officers, 387 ; College of Surgeons, Air raid damage to the, 637 ; Geographical Society, awards made to Capt. P. A. Clayton, Dr. I. Bowman, C. T. Madigan, A. Stephenson, M. Aurousseau and Capt. F. S. Chapman, 478 ; Institution, Election of Officers, 573 ; Meteorological Society, award of the Buchan prize to H. L. Wright, 145 ; Military Academy, the, 205 ; Observatory, Greenwich, Air raid damage to, 53 ; Sanitary Institute, Earl of Bessborough elected president of the, 673; Society: bequest to the, by Sir Henry Head, 84; Bequest to the, by Sir Robert Hadfield, Bart., 237; New Fellows of the, 383; election of Mr. Winston Churchill as a Fellow, and of Prof. J. B. Conant and Prof. K. Landsteiner as foreign members of the, 704; of Arts, award of the Albert Gold Medal of the, to President Roosevelt, 669; of Edinburgh: award of the Guning Victoria jubilee prize to Sir James Irvine and the Macdougall Brisbane prize to Dr. E. L. Ince, 174; Election of fellows, 295; of South Africa, election of officers, 85; Statistical Society, H. Leak appointed President of the, 237; Society, Mr. Winston Churchill admitted a fellow of the, 772; College of Surgeons, endowment of a Bernard Baron research professorship at the, 775; Anthropological Institute, award of the Rivers Memorial Medal to Dr. D. Jenness and of the Wellcome Medal to Dr. Audrey I. Richards, 800; Meteorological Society, 50th Phenological Report of the, 802

Rubber: Research Institute of Malaya, Sir Geoffrey Evans, 15; Planting Material, Improvements in, C. E. T. Mann, 150; and its many uses, H. McKay, 387; Recent Researches on, G. F. Bloomfield and E. H. Farmer; G. Gee and L. R. G. Treloar; G. R. Tristram; J. McGavack and C. E. Rhines, 752

Rust: the Mystery of, Dr. E. F. Armstrong (*Review*), 307; Fungi, Perennating, Alternation of Generations in, A. M. Brown, 644

Rutherford: Lord, Dr. N. Feather (*Review*), 724; the Hero as Man of Science, Prof. H. R. Robinson (*Review*), 724

Saccharum, Intergeneric Hybrids of, E. K. Janaki-Ammal, 361

Sailing the Skies, C. H. Latimer-Needham (*Review*), 38

St. Andrews University: Chemistry at, Sir James Irvine, 23; Handbook of the United College, 355

Salmon, Vitamin Content of, Dr. M. Pyke and Margaret D. Wright, 267

Sand Cays, Formation of, J. A. Steers, 91

Sandal, Spike Disease of, S. R. Iyengar and A. L. Griffith, 385

Sandstones, Cross-lamination in, E. D. McKee, 271

Saxon Relics from Lincolnshire, T. Sheppard, 330

School Certificate Candidates, Concessions to, 112

Science: and Government, R. H. F. Finlay, 119; Cultural Significance of, Prof. M. Polanyi, 119; and Military Service in the U.S.A., 142; and a New World Order, Prof. J. D. Bernal, 143; and the Unobservable, Dr. A. J. Lotka, 149; Students at Universities and Schools, 172; and Government, Dr. V. B. Wigglesworth, 206; Cultural Significance of, Dr. C. H. Waddington, 206; Museum, Bequest to the, by Sir Robert Hadfield, Bart., 237; National and International, and the Basis of Co-operation, Prof. A. V. Hill, 250; Politics and Government, 275; and Government, Dr. E. C. Childs, 298; Dr. O. Blüh, 299; Museum, Air raid damage to the, 352; Philosophy and Religion: a Symposium, 367; Masters Association, Report for 1940, 386; and Government, Prof. J. A. Crowther, L. Pendred, 415; R. H. F. Finlay, 416; be Independent?, Can, Prof. J. B. S. Haldane 416; and the National Effort, Lord Hankey, 432; and Democracy, 448; The Man of, as Aristocrat, H. G. Wells, 465; in Modern Life, 551; in the Totalitarian State, W. Kaempffert, 570; Dictionary: French-English, for Students in Agricultural, Biological and Physical Sciences, Prof. L. De Vries and others (*Review*), 625; The Social Message of, Prof. M. Polanyi, 637; and Society, Dr. H. Nicol, 808

Scientific: and Technical Books, Recent: January 25, iv; February 22, iv; March 29, iv; April 26, ii; May 31, ii; June 28, ii; Centenaries in 1941, Eng.-Capt. E. C. Smith, 17; Workers, Reservation of, W. L. Stevens and Dr. A. C. Fabergé, 28; Workers, Selection of, Dr. C. S. Myers, 155; Research, War and, J. M. Watson, 321; Co-operation between Great Britain and the United States, 384; Administration in National and Local Government, 489; Liaison with America, 537; Workers, Association of, Annual Council Meeting of the, 707

Scorpion, Unusual Mitosis in a, I. Sato, 150

Scotland, Vital Statistics of, 55

Scottish Department of Health, Sir Andrew Davidson appointed Chief Medical Officer of the, 237

Seismic Prospecting, A Plutonic Phase in, L. D. Leet, 645; Velocities, Variation of, within a Simplified Earth Model, F. Birch, 783

Seismology, Data of, 450

Selection, Experiments in, Dr. K. Mather, 331

Semimicro Qualitative Analysis, W. Ll. Evans, A. B. Garratt and L. K. Quill (*Review*), 559

Sensations, Discreteness of, Prof. S. Lifshitz, 390

Sensitive Flames, Effective Frequencies of, P. Savic, 241

Sesame Cake and Antler Growth, Prof. J. C. Drummond, Dr. A. W. Greenwood, R. R. Ridgway and P. C. Williams, 26

Sex Chromosomes, Evolution of, M. J. D. White, 809

Sexuality in Wild Populations, D. Lewis, 713

Sheep Tick and Sheep Maggot Problems in Great Britain, Dr. J. McLeod; Dr. R. P. Hobson; Dr. I. Thomas, 421

Sheffield University: Bequest to, by Sir Robert Hadfield, Bart., 237; Dr. S. A. Peyton appointed librarian, F. J. S. Esher assistant lecturer in Mental Diseases, M. Laird junior demonstrator in Anatomy and Mrs. Mildred John, part-time demonstrator in Anatomy; bequest by Mrs. E. G. Willis, presentation of the late Prof. R. V. Wheeler's published researches; resignation of Dr. F. E. E. Schneider and T. C. Joyce, 606; bequest to, by Sir Charles Clifford; Dr. V. M. Conway appointed an assistant lecturer, Dr. L. Leyton and A. N. Barker temporary demonstrators and Mrs. E. M. Harrison a part-time assistant in Botany, 775

Ships: Classification of, Progress in Marine Engineering as influenced by the, Dr. S. F. Dorey (Thomas Lowe Gray lecture), 264; Electrically driven, A. Regnauld, 304

Sierra Leone, Health of, Dr. W. P. H. Lightbody, 55

Silage, Feeding Value of, 236

Silica, Vitreous, Structure of, S. S. Lu and Y. L. Chang, 642

Slip Bands, Origin and Spacing of, Dr. E. Orowan, 452

Smith, Theobald, award, Dr. H. R. Cox, nominated for the, 451

Smithsonian Institution, Report of the, 539

Smut Fungi, Miss Kathleen Sampson: Dr. B. B. Mundkur, 419

Snow medal of the American Social Hygiene Association, award of the, to Mrs. C. Neville-Rolfe, 261

Social: Hygiene, Education in, 261; Reform: Programme for, Mrs. Barbara Wootton (*Review*), 558

Socialism and Federation, Mrs. Barbara Wootton (*Review*), 461

Sodium: Resonance Radiation of, Quenching of the, Dr. R. G. W. Norrish and W. MacF. Smith, 61: Hydride, Band Spectrum of, R. C. Pankhurst, 643

Soil: Solutes in Plants, Upward Movement of, Mason and Phillis, 210; Protozoa in some Chinese Soils, Prof. H. Z. Gaw, 390; and Sense, M. Graham (*Review*), 520; Fertility and National Health, Dr. R. O. Whyte (*Review*), 590; in the Field, The Study of the, G. R. Clarke. Third edition (*Review*), 761

Soils and Afforestation, Muir, Frazer and Steven, 300

Solar: Eclipse, 1940, Spectrographic Observations of the, R. O. Redman, 151; Prominences in Three Dimensions, Motion of, 331; Radiation, Measurement of, E. Rübel and W. Lüdi, 360; Variation, Periodicities in, Dr. C. G. Abbot (corrections), 414; Hydrogen Vortices, Nature of, R. S. Richardson, 579; Prominences, Motions of, Problems of the, M. A. Ellison, 662

Solids: The Modern Theory of, Prof. F. Seitz (*Review*), 623; Soft X-Ray Spectroscopy of, Dr. H. W. B. Skinner, 646; Electric Properties of, R. M. Fuoss, 715

Solvents, Industrial, I. Mellan (*Review*), 222

Soul: Mythology of the, a Research into the Unconscious from Schizophrenic Dreams and Drawings, Dr. H. G. Baynes (*Review*), 74

TITLE INDEX

d, Reproduction of, Principles of the (*Review*), 311
h : Africa, High Commissioner of, Lord Harlech appointed, 262 ; African Geology, Dr. L. T. Nel and others, 361 ; Native Life and Problems, Select Bibliography of, compiled under the direction of I. Schapera (*Review*), 525 ; Fireclays, The Rarer Constituents of, V. L. Bosazza, 747 ; America, Economic Geography of, Prof. R. H. Whitbeck, Prof. F. E. Williams, assisted by Prof. W. F. Christians (*Review*), 728
Southern Rhodesia, The 'Great Dyke' of, O. Weiss and others, 749
Soviet Agriculture, 354 ; Russia, 787
Soya Bean Culture in Great Britain, Dr. H. H. Mann, 660
Species, New, Publication of, Hon. Miriam Rothschild, 676
Spectrochemical Literature, 606
Spirit, Surgical and Hospital, need for economy in the use of, 740
Starch Molecule, Repeating Units in the, Linkage between the, Prof. C. C. Barker, Prof. E. L. Hirst and G. T. Young, 296
Star-Streaming and Spectral Type, Dr. W. M. Smart and T. R. Tannahill, 61
Stars : Philips' Chart of the, Edited by E. O. Tancock (*Review*), 74 ; White Dwarf, Internal Temperature of, R. E. Marshak, 211 ; and Atoms, Prof. J. A. Crowther (*Review*), 689 ; near the North Pole, Reddening of, Keenan and Babcock, 750
Statistical : Calculation for Beginners, E. G. Chambers (*Review*), 70 ; Reasoning, Elements of, Prof. A. E. Treloar (*Review*), 70 ;
Statistics : Mathematics of, J. F. Kenney, 2 parts (*Review*), 70 ; Theory of, Aspects of the, M. G. Kendall (*Review*), 70 ; and Prime Numbers, Prof. A. Wintner, 208
Stearic Acids, Isomeric Dihydroxy- and Tetrahydroxy-, Rates of Oxidation of, by Lead Tetra-acetate, Prof. T. P. Hilditch and Dr. H. Jasperson, 327
Stereochemical Types and Valency Groups, N. V. Sidgwick and H. M. Powell (Bakerian lecture), 301
Sterkfontein Ape : Structure of the, Dr. R. Broom, 86 ; Hand of the, Sir Arthur Keith, 146
Steroids, Chemistry of the, X-Ray Crystallography and, Prof. J. D. Bernal, D. Crowfoot and I. Fankuchen, 680 ; Pentacyclic, Dr. O. Rosenheim, 776
Stockholm Technical Museum, The, 572
Stone : Age Man in Ceylon, 392 ; Implements from Ceylon, H. V. V. Noone, 419
Stress-Strain Hysteresis in Certain Clays and other Substances, H. H. Macey, 146
Student Teaching : an Experience Program, R. Schorling (*Review*), 555
Submarine Canyons, A. L. du Toit, 151
Sugar-Cane Field Experiments, P. E. Turner, 645
Sulphonamides and their Derivatives, Action of, on Bacteria, Dr. M. Mandelbaum, 266
Sun : The Birth and Death of the, Stellar Evolution and Subatomic Energy, Prof. G. Gamow (*Review*), 689 ; the, as a Producer of Energy, Prof. S. Chapman (Kelvin Lecture), 792
Sunspot, an active, 295
Supervisors and Foremen, The New Techniques for, Prof. A. Walton (*Review*), 592
Surface Tension and the Spreading of Liquids, Dr. R. S. Burdon (*Review*), 659 ; Cables, Design of Joint Boxes for, C. E. Rose, 810
Swahili-Botanical-English Plant Names, Dictionary of, Greenway, second edition, 354
Swammerdam medal, award of the, to Prof. G. W. Grijne, 295
Swedes, Rhizoctonia Rot of, R. W. G. Dennis, 87
Swine Influenza in Britain, F. Blakemore, 605
Swiss Electrochemical Industry during war-time, 803

Tadpoles Out of Season, H. Metten, 390
'Take-All' Fungus on Oats, Elizabeth M. Turner, 420
Tata, Lady, Memorial Fund, awards of the, 804
Tea : Growing in U.S.S.R., 173 ; Ceylon, Fermentation of, J. Lamb and H. B. Sreerangacher, 271
Telecommunications : Application and use of Quartz Crystals in, C. F. Booth, 212 ; Technique and Broadcasting Receivers, 212
Telescope, The 200-in., Dr. H. Spencer Jones (Thomas Young Oration), 753
Television Engineering, Principles of, D. G. Fink (*Review*), 221
Temperature Measurement, R. L. Weber (*Review*), 791
Tennessee Valley, Dam Construction in the, 153
Termite Investigations in Australia, F. J. Gay ; J. Greaves, 678
Tetraploids, Colchicine-induced, Obtained from Plants of Economic value, N. P. Baden-Nuizen, 577
Textile Testing : Physical, Chemical and Microscopical, Prof. J. H. Skinkle (*Review*), 222
Thinker, A Neglected, Prof. A. D. Ritchie (*Review*), 220
Thiocyanate, Ferric, H. E. Bent and C. L. French, 715
Thomson, O. M., Sir J. J., Lord Rayleigh, 241
Thorpe's "Dictionary", (*Review*), 39
Tiflis, Georgia, University, establishment of an Academy of Sciences, 804
Timber, Metal and Concrete Exposed to the Action of Sea-Water, Deterioration of Structures of, Dr. J. Newton Friend. Edited by H. J. Grose, 343
Time as an Imaginary Fourth Dimension of Space is Incoherent, Sir Joseph Larmor, 576
Tin, Superconducting, High-frequency Resistance of, H. London, 121
Tobacco Mosaic Virus Protein, A Quantum Yield for the Inactivation of, Prof. F. M. Uber, 148
Tomato Diseases, Soil-borne, Control of, W. Brown, 354
Tomatoes, Kromnek (Spotted Wilt) Disease of, Control of the, Dr. Enid S. Moore, 480
Toronto University : Prof. R. D. Defries appointed director of the School of Hygiene and of the Connaught Laboratories of, 24 ; gift to, by A. L. Wenner-Gren, 55 ; Tortugas Laboratory, The, Prof. K. M. Yonge, 341
Toxic Gases, Detection of, 265
Tradescantia, Inversions in, C. R. Swanson, 301
Transport : in Great Britain, Control of, 456 ; for War, Organization of, 457
Trees : Wayside and Woodland, a Guide to the British Sylva, E. Step. Revised by A. Keith Jackson and A. Bruce Jackson (*Review*), 659 ; Growing, Excavation of with Earth, F. A. F. Schmid and F. J. Nutman, 741
Triazine Complexes, Metallic, Dr. F. G. Mann, 778
Trichinosis in Britain, Dr. P. B. Beeson, 774
Trichosurus vulpecula, Renal Injury in, Produced by Œstrogens, A. Bolliger and A. J. Canny, 149
Trinidad and Tobago, Useful and Ornamental Plants of, R. O. Williams and R. O. Williams, jun., third edition, 686
Trisomics, Secondary, Origin of, M. M. Rhoades, 330
Tropical : Agriculture, Foundations of, Prof. C. W. Wardlaw, 282 ; and Subtropical Diseases, Institute for, opened at Modena, 355
Trout in New Zealand, Reproduction of, D. F. Hobbs, 270
Trunk Telephone Working, Automatic Equipment in, H. E. Humphries, 742
Tuberculosis in the Navy, Surgeon-Rear-Admiral S. F. Dudley and Surgeon-Commander W. G. C. Fitz-Patrick, 413
Tungsten, Molybdenum and, in the Caucasus, 264

Uganda : Agricultural Production in, J. H. Holland (*Review*), 691 ; Agriculture in, Edited by Dr. J. D. Tothill (*Review*), 691
Uintatherium, Discovery of a Fossil Skeleton of, Dr. C. L. Gazin, 114
Ullman, Fittig and, Reactions, Free Aryl Radicals in the, Dr. W. S. Rapson and R. G. Shuttleworth, 675
Ultra : Violet Light, Mutation Effects of, K. Mackenzie and H. J. Muller, 210 ; Perceptive Faculty : The, an Experimental Investigation, Dr. J. Hettinger (*Review*), 217 ; Exploring the, Dr. J. Hettinger ; Dr. E. J. Dingwall (*Review*), 658

Ulva lactuca, Isolation of Rhamnose Derivatives from, Miss M. M. T. Plant and Miss E. D. Johnson, 390
Union Observatory, Johannesburg, retirement of Dr. H. E. Wood ; appointment of Dr. van den Bos, 772
United States, Our, in this Backward Moving World, Dr. N. Murray Butler, 113
Universities : and the War Damage Bill, 237 ; and Man Power, Dr. R. Priestley, 263 ; Government Grant to, 263
Urea and Related Compounds, Molecular Anisotropy of, Dr. K. Lonsdale, 715
Urodele Larvæ, Changes in Amputated Nerveless Limbs of, O. E. Schotté and E. G. Butler, 780
Urosalpinx cinerea, the American Oyster Drill, Sex Ratio in, H. A. Cole, 116
U.S.A. : Science and Military Service in the, 142 ; and the Democratic Ideal, President Roosevelt, 142 ; Population of, 205 ; Education in, 235 ; Smallpox in, 265 ; British Medical Students in the, 322 ; Educational Work in the, T. Raymont (*Review*), 555 ; National Academy of Sciences, Prof. A. V. Hill elected a foreign associate of the, 573 ; Agricultural Regional Laboratories in the, Dr. R. O. Whyte, 597 ; Place-Names in the, Dr. J. P. Harrington, 604 ; National Academy of Sciences, Observations on the Members of the, Dr. A. Hrdlička ; Sir Arthur Keith elected a foreign associate member of the, 638 ; Public Health Service, formation of a division of Chemotherapy in the National Institute of Health of the, 708 ; National Academy of Sciences, recent elections to the, 772 ; award of the Henry Draper medal of the, to Prof. R. W. Wood, 775
U.S.S.R., award of the Order of Lenin to Prof. A. F. Joffe, 53 ; New Botanical Gardens of, 55 ; a 50-million volt cyclotron for the, 114 ; Tea-growing in, 173 ; Underground Gasification of Coal in the, 477

Valency Groups, Stereochemical Types and, Prof. N. V. Sidgwick and H. M. Powell, 301
Vanadium Ion Potentials, A. B. Hart, and Prof. J. R. Partington, 151
Vegetables as Food, Dr. M. Pyke, 513 ; V. H. Booth, L. W. Mapson and Dr. T. Moore ; Miss Mamie Olliver and W. B. Adam, 711 ; Dr. M. Pyke, 807 ; Miss M. Olliver, 808
Victorian Traveller (*Review*), 269
Victory : Foundations of, Lord Davies (*Review*), 518 ; Programme for, a Collection of Essays Prepared for the Fabian Society by Prof. H. J. Laski and others (*Review*), 558
Virus Inclusions, Blastogenic Agents and Ciliates, J. C. Mottram, 479
Viscosities of Three Classes of Liquids, G. N. Copley, 207
Vitamin : C, Oxidation of, Influence of Purines, Creatinine and Creatine on the, Dr. K. V. Giri and P. V. Krishnamurthy, 59 ; A, Alcohol and, Drs. S. W. Clausen, B. B. Breeze, W. S. Baum, A. B. McCoord and J. O. Rydeen ; Dr. L. B. Pett, 323 ; D, Influence of, upon the Incisor Teeth of Rachitic Rats, Prof. J. T. Irving, 608
Vitamins A and E, Interaction of, A. W. Davies and Dr. T. Moore, 794

Walden Inversion, The, in the Replacement of Hydroxyl by Halogen, Dr. E. D. Hughes, Prof. C. K. Ingold and I. C. Whitfield, 206
Wales, Early House-types in, Sir Cyril Fox, 120
War : by Revolution, F. Williams (*Review*), 2 ; -time Formulary, a committee on, 54 ; The Origins of the, E. L. Woodward, 234 ; and Treaties, Dr. A. D. McNair, 293 ; -time Communications, Minister of, F. J. Leathers appointed, 602
[illegible]rming of Buildings, Early Application of Engineering to the, A. F. Dufton, 324

NATURE

"To the solid ground
Of nature trusts the Mind that builds for aye."—Wordsworth

Vol. 147 SATURDAY, JANUARY 4, 1941 No. 3714

COLLABORATION IN EUROPE

FROM time to time in the past few months, reference has been made in these columns to the need for consideration of the reconstruction which will have to be faced after the War. The King, in his Christmas Day broadcast, referred to the new unity which comes from common perils and common suffering endured, and pointed out that we must hold fast to this spirit of unity in the days to come, both in our own lives and even more among the nations. The Archbishop of Canterbury has stressed the urgency of reconstruction problems. Let there be no mistake. If they are given the time, the Nazis can and will build a new order in Europe embracing not only France but also those other countries on which their tyranny has in succession descended. That will not be an order for free men, and its basis, as Mr. Bevin pointed out in a recent vigorous address, will be the racial superiority of the Germans.

The two outstanding characteristics of the War are indeed, first, that it is in substance a civil war, and secondly, that the conditions which led to its outbreak will not be cured or reformed merely by victory and the rehabilitation of pre-War Europe. To the first the presence, legalized by the Allied Forces Act, in Great Britain of six foreign armies, training under their own flags, their own commanders, their own military law, testifies. We must also count among the freemen of Europe the Germans, Austrians, Italians and Spaniards who are still eager to serve as pioneers and sappers for the intellectual engineering jobs of the War and post-War, as well as the many refugees now being mobilized for technical service through the International Labour Branch of the Ministry of Labour.

From this derives our right and responsibility in opposing the Nazi regime to call upon the love of liberty and respect for human rights all over the world and make ourselves their champion. This involves, as Mr. Bevin so clearly insisted, the readiness to face great changes in our own society. Further, our present propaganda seems to be handicapped by lack of understanding of democracy in Europe, and until we show ourselves in the War and in our plans for the future more of a democratic nation, we shall not fire the imagination of Europe or of our own society in a way that is commensurate with the leadership devolving upon us.

Consciousness of this is clearly betrayed in Mr. Bevin's recent speeches, and lies at the basis of the demands being voiced for an official statement of our own war aims. A statement of the basic principles which we intend to see embodied in the new world order is an important contribution to that end, and an assurance that a Cabinet committee is working unremittingly on a design for twentieth-century living, in the sphere of international affairs as in that of reconstruction at home, might reasonably be asked.

Some token or expression of the forward-looking mind and an indication that the research and investigations and fundamental thinking about the problems really involved are the first essentials towards developing relations with the submerged democratic movements abroad, is the theme ably argued by Mr. Francis Williams in his "War by Revolution"[1]. Mr. Williams argues that we can achieve our main object in the War by adopting the strategy of revolution. We must disrupt the Nazi system from within by appealing to the vast numbers of men and women, both in the occupied countries and in Germany itself, who are on the side of democracy against authoritarianism. This involves re-stating the democratic faith as a revolutionary faith, and taking the offensive everywhere, using those elements of the population in every country in Europe who are on the side of a new and true democracy.

This is also the theme of a series of world order papers recently published by the Royal Institute of International Affairs[2]; but the outstanding impression left by these papers is the distance we have yet to travel and the amount of work, both educational and research, which must be carried out before we can look for the establishment of a new order. There can be no international reconstruction, no establishment of a new world order, unless, as Sir John Fischer Williams argues in his outline of the minimum requirements of an effective federation which may be possible at the end of the present War, the minds and wills of those who command the obedience and embody the desires of humanity are set with friendly purpose to the achievement of the task. For all their lucidity and moderation, neither Sir John Fischer Williams nor Sir William Beveridge in his paper on peace by federation, are really any more convincing in their exposition of federation than Mr. R. G. MacKay's excellent "Federal Europe". For this there are two causes. First, the advocates of federalism have as yet scarcely dealt in any adequate measure with its practical difficulties. This can indeed be due in part to the tentative approach to the problem characterizing the soundest and ablest of its advocates. It may be due much more to the difficulty of finding an adequate basis in common interests, traditions, habits of thought, language, geographical continuity or the like, without which, as Prof. Gilbert Murray points out, a federation can scarcely maintain itself at all.

It follows from this that, should obstacles make actual federation at the end of the War unattainable, other steps must be taken for preserving the general peace. Sir William Beveridge, in discussing an approach to the German people, to be used possibly in such ways as Mr. Williams indicates, suggests indeed that we should state frankly our willingness to consider alternative proposals from the other side for the elimination of war, and he lays stress on the need for eliminating all sense of injustice and for handling the colonial and economic problems of the world on lines designed to that end as well as to the improvement of the standard of living. A first step towards the latter would be an International Reconstruction Commission, coming into action on the day that fighting stops, and charged with the duties of relieving distress, repairing war damages, and re-establishing prosperity for all at the common charge of all. One characteristic of these papers is, indeed, the consensus of opinion as to the importance of building on what foundations already exist and have proved their value.

The second point on which the consensus of opinion is remarkable is the necessity of some positive attempt to diminish the economic causes of war. Mr. P. Horsfall, in a paper entitled "Doubts as to the Imminence of the Millenium", remarks that it is neither a futile nor a mean ideal to work for this end through the co-operation of sovereign communities, without endeavouring to merge their distinctive national loyalties in a forced allegiance to a new State. The institutions and aims of any new association of nations must have regard not only to the hopes but also to the experience of mankind. Prof. L. Robbins's paper is indeed devoted to the economic factors tending to make for international diversity, and he shows that the great danger is not planning in general but independent planning by independent States. While he looks on the idea of complete and immediate federalization of all Europe immediately after an armistice as based on a delusion, he urges that out of the close associations of the present conflict there may come some permanent nucleus of stability, with sufficient power to ensure a breathing space in which the building of a more extensive organization may proceed with due care and circumspection.

There can be no doubt either that great difficulties will have to be overcome to establish a new European order; or as to the necessity of establishing some effective form of international co-operation, whether in a federal system or some modification of the League system. The plans for rebuilding Europe must be well thought out and carefully laid long before the opportunity of rebuilding arises. If Europe is to pass from an international system of conflict and war to one of law and co-operation, the machinery of its organization, as Mr. L. Woolf truly remarks in "The War for Peace", must be such as encourages the growth of the psychology of internationalism at the expense of the psychology of nationalism. This attitude forms the starting-point indeed for the offensive propaganda outlined alike by Mr. Williams in "War by Revolution" and in the pamphlet "How We Shall Win" issued by Federal Union[3]. We can only hope to play our full part as champion of freedom and of that part of mankind's great heritage which derives from the creative powers of individuality and respect for human personality when we can show the world that we can offer a programme of freedom and reconstruction to meet twentieth-century needs.

QUI S'ACCUSE S'ACQUITTE

A Mathematician's Apology
By G. H. Hardy. Pp. vii + 94. (Cambridge: At the University Press, 1940.) 3*s*. 6*d*. net.

THIS is a slight book. From such cloistral clowning the world sickens. It purports to be an apology for a life misspent in mathematics and for the sort of mathematics on which it has been misspent—'real' mathematics as the entirely useless and to the 'real' mathematician the more profound part, in contradistinction to the 'trivial' part, in the culprit's view ugly in some sort of direct ratio to its usefulness. "Anyone who defends his subject will find that he is defending himself," and the last chapter is autobiographical. The court is of opinion that no such charge ought ever to have been or ever has been brought, and that it is unwise for the defendant to undertake the conduct of his own prosecution.

It is a personal vindication—much in the spirit an artist might confide in the public—defending himself and his particular clique, the 'real' artists[*], from a possible charge of wasting their talent and explaining their curious canons of beauty and ugliness. As he himself states, few subjects are more popular than mathematics, and probably, if the truth were known, more people are interested in it than in music; there are masses of chess players in every country and chess problems are "the hymn tunes of mathematics"; it pleases even men who have used disparaging language about it; and in this shameless pastime few could rival the author. "School", "Hogben", "repulsively ugly", "intolerably dull" are his synonyms for "trivial" in dealing with the less mystical parts of it. Of the other sort one gets the impression that their real place is neither a university, technical college nor art school, but a place of worship. Naturally he is a little more enthusiastic about "mathematical physics, a splendid subject with tremendous problems where the finest imaginations have run riot". As regards what he calls "atomic physics", before it fell among mathematicians it was called radioactivity, and was not altogether without a certain crude loveliness, as it sprang from chemistry, physics and geology, almost full grown. But since it entered the beauty-parlour of $\sqrt{-1}$—for the benefit of the unlearned, a talisman that generalizes gyration and getting there—its progress could scarcely be beaten by a young puppy chasing its own tail.

'Imaginary' universes are so much more beautiful than this stupidly constructed 'real' one, according to the author, and if by 'real' he means the Aunt Sallys stuck up and knocked down at successive annual science junketings in the attempt to get physical science into a mathematical strait-jacket, who would deny him? His chair as a collection of whirling electrons, for example, is not a little moth-eaten, for matter re-materialized long since, and is at the moment said to be mainly made up of neutrons. But the spectacle of science also and already beginning to grin through a horse-collar at itself in its vanity bag must have warmed, within their protective endowments, the mummified hearts of all Olympus' faded hierarchy. Most scientists, however, still believe that the saner outlook on Nature inaugurated by the experimental sciences does reveal the real universe, and that it is not stupidly constructed. Those of them duped by mathematical fantasy are to be put up with rather than pukkha'd.

But there would be a graver charge to answer if the defendant had not constituted himself counsel for his own prosecution, on the question of the relative harmlessness, beauty, utility and so on of trivial and make-believe mathematics. Counting and calculation are good servants, capable too, like art and music, of giving pleasure

[*] The student should make himself thoroughly familiar at an early stage with this simple method, known even in antiquity, of raising the second order of small quantities to Pukkha magnitude, as until proficiency is attained his progress will be laborious.

to those so minded as well as to professional performers; but in a world ruled by the counting-house rather than by physical and biological laws, they are bloody masters. The Hindu mathematicians, to whom we owe the first use of imaginary negative quantities, justified them by their analogy to debts. They had not then risen to the heights of being able to think in minus pigs. They used them simply to denote a diminishment of the number of positive pigs, which the then elementary conception of common sense demanded had first to be taken for granted. But they put into the hands of the eternal word-spinners a weapon able to falsify physical accountancy and send a scientific civilization off the rails. Yet this incredible little book is largely a homily on the purity and beauty of mathematical philosophy, which thanks itself it is not like common sciences, trivial mathematics, engineering and chemistry, being preserved by its very uselessness from the evil association of war. Make-believe mathematics has led to make-believe finance, and in relative destructive power the chemist's bomb is a squib by comparison with an imaginary quantity divorced from common sense.

The humble road surveyors who converted the abacus into a calculating machine, and the primitive mule-track into the *autobahn*, stuck up a mirror marking the end of it to assist them in their triangulations. They found it such an assistance that they failed completely to understand its danger to road-users or the necessity of putting up a warning sign. In time they became philosophers and roundly declared that what was behind the looking-glass was much more real than what was in front of it and that there "one at least of our nobler impulses could escape the dreary exile of the actual world". Now when a high-power civilization has crashed straight into it they congratulate themselves that theirs at least is "a harmless and innocent occupation".

This book is also in some way a repartee to Hogben's "Mathematics for the Million". For the benefit of those acquainted with neither, it may be said that Hogben, winnowing perhaps the only grain of truth in Marxism, sees in the social environment and needs the inseminator of mathematical discovery, whereas Hardy confesses, as if to a defect, that "there is no mathematician so pure that he feels no interest at all in the physical world, but in so far as he succumbs to it he is abandoning his purely mathematical position". More briefly the "real" mathematician is a religious maniac, and who can be expected to subscribe to the view that a religion, whatever it is, is "harmless"? Marxism certainly is not, and the only one approaching this one in its renunciation of the world is Buddhism. Under it, in India, the multitudes starve and swarm, a curious biological correlation, to which attention was directed by Adam Smith in the case of the poor Scottish crofters, but in India operating in a warmer climate. On the other hand, *our* efforts to subordinate physical to mathematical reality are at the moment taking a stormier course; but in the heat of conflict no one is likely to remember the proverb of the devil among the tailors.

Hardy's view that the motive of research is not conscious intention to benefit humanity, but intellectual curiosity, pride of craftsmanship and ambition will, of course, be generally endorsed in research circles; but it is not inconsistent with detachment having proved sterilizing and necessity stimulating, nor with the direction of discovery being dictated by the prevalent trend of social inquiry. But his paradox that the useful subjects are just those most useless to learn, "a little chemistry or physiology having no value at all in ordinary life", their utility being confined to their practice by the few who specialize in them, they themselves being educationally useless, is typical of the effects on education of any religion with its inverted order of sequence of body, mind and soul. If children had been taught at their mothers' knee they were primarily little internal combustion engines, which, scientifically fed and maintained, would in time develop mind and soul and beget other children, mathematicians and other magicians would not find it so easy to get across their slanders. Chemistry at least would have come into its own. Instead of making bombs it would be esteemed for its creative rather than destructive aspect. At present it is a mere butler to the 'real' philosopher, and jackal to the riotous imagination of the mirror-image of that king of beasts.

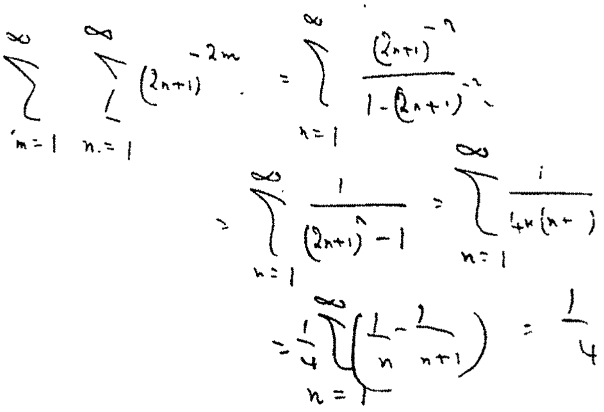
On this burning question of war, both Hardy, his critics whose criticism he thinks worth a special note at the end, and his opposite number are quite conventional. Hogben's "civilized people regarded war as a degenerate act of piracy" seems from a biologist and historian somewhat superficial, though it was written some years before the present struggle for existence started. But Hardy, in the midst of it, can write about "evil" chemistry without specifying whether by evil he means making good ammunition or bad. "When the world is mad, a man may find in mathematics an incomparable anodyne" has not apparently any reference to Archimedes. Surely in these times a little appreciation of the military virtues, rather than the conventional vilification of the profession of arms, is called for by religious people of all sorts, especially since their sort of "education" is really at the bottom of the whole tragedy, and the chemist's bombs and poison-gas are such a heaven-sent whipping boy for their own.

To the experimental scientist, Hardy's treatment of the nature of mathematical reality and his proof—from the primeness of a number—of it having external existence independent of the mind will be of interest. But as a guide he is as unreliable as the more popular exponents, and one gets the impression that outside his special subject—prime numbers—he can know little of it and cares less. He is merely a little more clever in concealing how the reader, usually by some pretty analogy, which no one could describe as mathematical, is made to take the false step himself. Thus we find before the proof from primeness, just alluded to, mathematical reality extended already to imaginary "geometries", the whole question at issue being begged by a footnote (p. 64. * "We must of course, for the purposes of this discussion, count as pure geometry what mathematicians call 'analytical' geometry"), leaving the reader to infer that he could prove the independent existence of mathematical reality as easily for a negative prime as for a positive one. Discussing the complete abstract generality of mathematical concepts, he follows Whitehead in saying they refer to "just any old things". Does that mean none ? For that is what *in practice* it has undoubtedly come to mean. But 317 nothings are the same mathematically as any other number of nothings or none. "It is obvious that irrationals are uninteresting to an engineer, since he is concerned only with approximations and all approximations are rational". As engineers deal with the measurement of continuous variables in the inanimate world, one would have thought it the other way, that they were interested in irrationals, as in this science integers and their ratio are positions without feature on a continuous line ending in a mirror, just as a biologist dealing with number for enumeration in the animate world has no use for fractions, rational or irrational.

In fact, the profounder the mathematician, when he reverts to everyday language, the less he seems able to talk it. They bore everyone to tears with their panegyrics over the profundity of the extension of the use of number from enumeration to calculation, which robbed them of any magic. They seem to treasure their most outstanding failures as remarkable achievements, and they impose on their wretched students a degree of formal rigour paralysing to the inventive capacity. Bertrand Russell's apocryphal dream, recorded in these pages, that he was in a university library about A.D. 2100 watching the assistant dumping all the old books off the shelves into a bucket and pausing a little over the last surviving copy of the "Principia Mathematica", is to-day at Oxford no dream but fact. But it is not the assistants—they weary of retrieving them from the cellars—it is prim and proper Prof. Hardy and his fellow purists, protecting the tender minds of their budding prodigies from loose thinking. They really should be barred from access to the shelves if their real purpose is to hunt out mathematical pornography. But there is a worse fate for a grand old mathematical text-book than the dump. It may be considered worth re-editing.

FREDERICK SODDY.

Postscript. The reviewer may have laid himself open to the retort that he has given no indication of what he considers real mathematics really is. As Huxley remarked, when you want to test the strength of a gymnast you do not ask him to lift a 200-lb. pair of dumbbells (such, for example, as is being dealt with in the hieroglyphics on the dust-sheet of this book, from "Asymptotic Formulæ in Combinatory Analysis" by G. H. Hardy and S. Ramanujan, which the publishers have thought the best way of frightening the public into buying it), but a 10-lb. Indian club *to see what he can do with it.*



$$\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}(2n+1)^{-2m} = \sum_{n=1}^{\infty}\frac{(2n+1)^{-2}}{1-(2n+1)^{-2}} = \sum_{n=1}^{\infty}\frac{1}{(2n+1)^{2}-1} = \sum_{n=1}^{\infty}\frac{1}{4n(n+\ )} = \frac{1}{4}\sum_{n=1}^{\infty}\left(\frac{1}{n}-\frac{1}{n+1}\right) = \frac{1}{4}$$

On a glorious summer afternoon in 1931, misspent in a way for which even the author could scarcely apologize, attending a faculty meeting, to improve the anything but shining hour of imprisonment the reviewer slipped across a note to the author, demanding the sum of all the reciprocals of each of all the odd integers, except unity, raised to the power of each of all the even integers, a question which the veriest tyro must admit is scarcely up to scholarship standard. After a surprised and concentrated stare of disgust at this common and probably poisonous insect, he started jabbing it with a pencil, viciously but cautiously at first, then with lightning ferocity as he chased it down the paper to the kill, and *in an incredibly short space of time* flung back the dead body here reproduced.

F. S.

TREES OF MALAYA

Wayside Trees of Malaya
By E. J. H. Corner. Vol. I. Pp. vii + 770. Vol. 2. Pp. ii + 228 plates. (Singapore: Government Printing Office, 1940). 10 dollars.

IT is, we believe, unique to find monkeys co-operating with a botanist in collecting flowering and fruiting specimens of trees for botanical investigation. This, however, has been done in Malaya by Mr. Corner, the author of the very interesting book under review, and his trained Berok monkeys, one of which is figured on the cover of the book, have provided him with much valuable material which otherwise might have been unattainable.

Some 950 species of Malayan "wayside" trees are described, and keys are provided for running them down to their families and genera. Anyone, therefore, who is interested in the trees, and is not a botanist, should be able to determine them without much difficulty, more especially as the distinguishing characters selected can be readily observed and are available throughout the year. The book is greatly enhanced by more than 250 excellent illustrations of different trees, which comprise the second volume.

The first volume consists mainly of descriptions of the various trees, accompanied often by useful text figures of flowers, fruits, and leaves, and keys to the genera and species, and much interesting information is given about the trees and their uses, and also about the vegetation of Malaya.

The book, in addition, includes a descriptive account of trees and how to name them. Forty pages are occupied by the elaborate keys, which are constructed on somewhat original lines. Mr. Corner has, in some cases, sacrificed clearness and accuracy for the sake of brevity in his constant use of the words "not so" as the alternative phrase in the couplet of distinguishing characters. In the first place it is not always easy to appreciate to what it applies, and in many cases it certainly does not apply to the whole of the statement with which it is contrasted.

Another unusual feature of the book is the arrangement of the families and the genera in alphabetical order. This may serve a useful purpose, but it is very disturbing to the botanist, since it brings into juxtaposition families wholly unrelated to one another. The Gymnosperms, however, are relegated to the end of the volume.

The book is provided with excellent indexes of English, Malay, and Latin names, and the inclusion of derivations of the generic and specific names is very welcome.

The volumes are a credit to the Government Printing Office, Singapore. The printing of the text and the reproduction of the fine photographs leave nothing to be desired.

A. W. HILL.

AUSTRALIAN SHARKS AND RAYS

The Fishes of Australia.
Part I: The Sharks, Rays, Devil-Fish and other Primitive Fishes of Australia and New Zealand. By Gilbert Percy Whitley. (Australian Zoological Handbook). Pp. 280. (Sydney: Royal Zoological Society of New South Wales, 1940.) 7*s*. 6*d*.

THIS useful handbook deals, not only with the Selachians (sharks, rays and chimaeras) of the seas of Australia and New Zealand, but also with creatures such as the lancelets, lampreys and hagfishes, and the unique lung-fish of Queensland. It is complete in itself, but is designed to form the first of a series of volumes on the fishes of Australia, which, when complete, should go far towards providing a long-standing desideratum. Within the compass of some 160 pages, the author has managed to include a brief description and figure of every known species of shark and ray, together with notes on its local range, maximum size attained, and so on. It is perhaps to be regretted that keys are not provided to assist identification of specimens; but the excellence of most of the illustrations, based almost entirely upon authentic local specimens, should serve to compensate for this omission. There can be little doubt that the intelligent reader making use of the systematic section of this book should have very little difficulty in determining most of the fishes likely to come to hand.

In addition to the systematic part, however, Mr. Whitley has managed to bring together a mass of valuable information concerning sharks and rays in general, which is presented in a comprehensive and interesting manner in the first sixty-seven pages of his book. This covers not only the breeding habits, development, anatomy, teeth, food, and so on, but also more unusual subjects such as sharks in mythology, sharks in captivity, their commercial uses, and their attacks on man. The section dealing with shark attacks and tragedies is of special interest, although it makes grim reading. The correlation between the temperature of the sea, with the consequent popularity of swimming as a sport and the extension of the bathing season, and the liability of man to attacks from sharks is stressed, and the comparative rarity of such tragedies in the cooler waters of Britain explained.

The chief criticism of this book is concerned with its nomenclatorial features. The author's fondness for minute generic and subgeneric groupings, and for pouring endless new names into the already overburdened ichthyological synonymies, is well known, and has caused considerable concern to workers on fishes in all parts of the world. The more conservative reader will be more than a little puzzled by the names applied to familiar Australian sharks and rays. It will come as a shock, for example, to find the closely related species of spiny dogfishes, referred by most workers to the Linnæan genus Squalus, here designated *Flakeus megalops*, *Flakeus griffini*, *Koinga whitleyi*, *Koinga kirki*, etc. Again, the spotted dogfishes have been regarded by a distinguished European authority as constituting a single genus (Scyliorhinus), although others would be willing to recognize some four natural groups as genera: in the present work the Australian species alone bear six different generic names. The introduction of still more new specific, subgeneric and generic names in this book, which is admittedly of a semi-popular nature, is to be deprecated.

J. R. NORMAN.

METAPHYSICS REDISCOVERED

An Essay on Metaphysics

By R. G. Collingwood. (Philosophical Essays, Vol. 2.) Pp. x+354. (Oxford: Clarendon Press; London: Oxford University Press, 1940.) 18*s*. net.

IN this book Prof. Collingwood is trying not to redefine metaphysics but to define it truly. That is to say, he is setting himself the task of elucidating its essential nature—that by which it has had significance for every age in which it has flourished. His book is therefore an apology for metaphysics rather than for metaphysicians. Indeed, as is to be expected from its aim, it also provides an apology for what the author terms "progressive anti-metaphysics"; that is, the reaction experienced by living minds at any given time against the work produced by those professional thinkers who have the prescriptive right to be called metaphysicians, but who do not clearly understand their work. "It is only confusion as to what he is about," says the author, "that makes the metaphysician's work harder than that of other scientists" (p. 84). For metaphysics is essentially a historical science; and it is this aspect of its definition which is so liable to be forgotten.

The first part is concerned with the work of definition. Taking the metaphysic of Aristotle, the author shows that this reveals two possible definitions: (1) that metaphysics is the science of pure being; (2) that it is the science which deals with the absolute presuppositions underlying ordinary science. He disproves (1) on the ground that it is a contradiction in terms; for the universal of pure being is the limiting case of the abstractive process, while it is the function of a science to investigate the particular—a statement which may lead some philosophers to argue that, though undoubtedly true of modern science, it does not necessarily define science as the Greeks understood it; and that therefore the contradiction is convincing only if science is understood in the modern sense. Working on the second formula, the author goes on to a very valuable chapter on the nature of presuppositions, distinguishing between those which are relative and those which are absolute. Absolute presuppositions can never be answers to questions, because all questions involve some sort of presupposition. Hence the distinction of truth and falsity cannot apply to absolute presuppositions; that is, far from being propositions themselves, they form a condition necessary to all propositions. Going on to study the nature of absolute presuppositions, Prof. Collingwood comes to the inevitable conclusion that metaphysics is "the attempt to find out what absolute presuppositions have been made by this or that person or group of persons, on this or that occasion or group of occasions, in the course of this or that piece of thinking" (p. 47). It is its nature as a ***historical*** science which decisively differentiates metaphysics from theology. Theology sets out presuppositions which are to be accepted by faith: metaphysics studies historically those presuppositions which are in fact accepted in each successive era of thought. As regards the immunity of their subject-matter from examination as to its truth or falsity, each agrees.

The second part of Prof. Collingwood's book is concerned with anti-metaphysics and pseudo-metaphysics. Anti-metaphysics may be progressive, reactionary, or irrationalist ; and pseudo-metaphysics confuses absolute with relative presuppositions. In the light of these distinctions, psychology is considered as anti-metaphysics and as the pseudo-science of thought ; but it is a pity that Prof. Collingwood, in common with most philosophers, judges the present science by its philosophical antecedents, while it is a characteristic of modern psychology that those antecedents are nominal only. Is not the author here falling into one of the very pitfalls which he has hitherto stated to be a source of confusion to metaphysicians ? Many psychologists certainly fall under the heading of anti-metaphysicians—but *progressive* anti-metaphysicians. Is it not the task of the metaphysician to examine the presuppositions of psychology as it stands to-day, rather than to judge it in the light of outworn definitions and a misleading heredity ?

The third part of the book under notice is devoted to examples and illustrations based on the ideas of the first two parts. For example, there is an examination of the relationship between the European "scientific frame of mind" and its religious institutions, which, says Prof. Collingwood, are the guardians of the presuppositions upon which it has flourished. The latter part of the book is devoted to an examination of the philosophy of Kant, and an analysis of the idea of causation.

It is a characteristic of living works that they themselves are illustrations of the principles which they express in words. This is eminently true of Prof. Collingwood's very stimulating book. In his own words, "for a man of the twentieth century it is inexcusable to take a metaphysician's word for what he is doing. You must settle that question yourself by studying his works" (p. 235). It is not therefore surprising to find here illustrated the difficulties which beset the twentieth century metaphysician faced with the problem of modern psychology.

B. M. BALDWIN.

WORLD HISTORY

The Golden Ages of History
By Joseph McCabe. Pp. xi+242. (London: Watts and Co., Ltd., 1940). 10*s*. 6*d*. net.

IT is surely rather a mistake to use the term 'Golden Ages' as if it had any generally accepted or scientific meaning. It is rather like so many of the current slang words about an airman's achievements. Something or somebody strikes the speaker as exceptionally good, and he uses the phrase to characterize fifty or a hundred years of history or a long and exciting flight. In this way Louis XIV managed to gild some hundred years of French history, Queen Victoria not quite so much, and Queen Elizabeth still less. There is thus a profound fallacy in comparing or using the same terms of Queen Elizabeth's reign and the hundreds of years of China's flowering under the Tang and other emperors. Readers will also be inclined to jib at the exalted position assigned to the last hundred years of European history, considering that it includes at least five periods of disastrous fighting, and that it has culminated in the present War, which leaves us in grave doubt as to how much of Mr. McCabe's quite justly lauded triumph of science will survive.

These faults or queries about the book will strike every reader as soon as he opens it. But it would be a grave mistake to discard the wisdom which is often intermingled with the author's fallacies and prejudices. In the first place, it is a useful thing to have in one compact volume the mass of historical facts concealed in learned tomes, and to have them spread out chronologically, even if not in equal measure. British people are shockingly ignorant of history as a whole. It takes a war like the present to arouse us to a sense of our own historical greatness, and much of Mr. McCabe's book is entirely unknown, even to schools or scholars who 'do well' or are 'keen about their history'. It is a ridiculous and quite unnecessary fault in our school curricula which derives from the medieval fact that history was regarded merely as the chronicle of kings and popes down to nearly five or six hundred years ago. Summaries or conspectuses of the whole were always wanted, just as a globe has always been a necessary part of every school's equipment. Here is the place for such books as that of Mr. McCabe and of Mr. H. G. Wells. We would only plead—and every teacher will agree—that the 'book-globe' of history should be freer from prejudice, should aim at a simpler and less highly coloured picture than Mr. McCabe gives.

One might be allowed to suggest two or three of the essential features of such a 'general history'. It should be comprehensive, as Mr. McCabe has tried to make his. There is no acceptable reason why the outlines of Chinese or Indian history should be completely ignored. But it may be fairly at the same time rather more Western than Eastern, considering that, in the main, Westerners will read it, and that Western methods of government and education continue to spread over the world. Then there are two points on which I am happy to agree entirely with Mr. McCabe. The first is that our view of history from the first should cover all classes, and not the eminent or wealthy who fill the larger place in the older books. This does not mean that art or beautiful things should be ignored, but that they should be regarded as part of the patrimony of the poor as well as of the rich. The second, and perhaps most important of all the aspects of history, is the growth of knowledge and the use of knowledge for the welfare of mankind. On this point Mr. McCabe is sound and strong. What he needs is a kindlier and truer realization of the place of religion in history, and the value of religion to the poor as well as the aspiring, both in the East and the West.

F. S. MARVIN.

FROM COUNTING TO THE CONTINUUM

Number: the Language of Science
By Prof. Tobias Dantzig. Second revised and enlarged edition, based on the third American edition. Pp. xi+320+11 plates. (London: George Allen and Unwin, Ltd., 1940). 10*s*. net.

PROF. DANTZIG'S title raised my hopes. As a biometrician concerned in an attempt to substitute mathematical expressions for such useful, if slightly vague, biological expressions as race, type, heredity, and variation, I hoped that he might show why science is inevitably and progressively doomed to use mathematics as its language. He might even furnish me with arguments to be used on my non-mathematical colleagues.

I was disappointed. The book is written from a historical angle, and shows how the concept of number grew from the stage of finger-counting to transcendental and complex finite numbers, and transfinite cardinals. Practically nothing is said of further generalizations such as vectors and Kronecker ideals, though the former at least have more place in the language of science than transfinite cardinals.

The historical survey is full of interesting quotapions, and illustrated by an excellent series of portraits, but it is somewhat over-simplified. Thus, on p. 30 we read that the Greeks did not create even a rudimentary algebra, and that positional numeration originated in India. This enables the author to evade the very interesting questions of why Diophantus's algebra remained rudimentary, and why the Babylonians, who used positional numeration to some extent, did not invent zero or the decimal point.

The account of Cantor's work is particularly clear. But the same cannot be said for the treatment of mathematical reasoning. On p. 66 we read that a conclusion is logically flawless, if "we have examined our premises and found them free from contradictions". Surely a less acquaintance than Prof. Dantzig's with the history of mathematics should have made him pause before he wrote this sentence. For two thousand years Euclid's axioms were supposed to be free from contradictions. But Prof. Dantzig's Chapter xi on transfinite numbers is full of awful warnings against pushing the assertion that the whole exceeds the part beyond its proper domain; and quite recently Gödel has shown that no system of axioms can be proved to be free from contradictions. It can be tested for hidden contradictions, but a failure to find them is no proof that it is logically flawless.

This book has its proper place, in the library of amateurs of mathematics, or of schoolmasters who wish to make elementary mathematics as interesting as possible. But it does not tell us why in some periods mathematics develops in response to the demands of science, and at other times independently. Thus, the first transcendental functions were invented because observations became sufficiently accurate to make them valuable. Then function theory ran ahead of practice. To-day science has caught up mathematics in many fields, and unfortunate biologists like Sewall Wright and myself are compelled to investigate probability distributions (one of the most interesting generalizations of number) because the mathematicians have not yet done the work for us.

Prof. Hogben, to take a recent and justifiably well-known example, has told us how mathematics grew up in response to scientific demands. Prof. Dantzig tells us something of how it grew under the stimulus of its own internal contradictions. I am waiting for an author who will combine these two points of view, and give us a real philosophy of mathematical progress; and I hope that when such a book is written it will be better bound than "Number".

J. B. S. HALDANE.

The Commissioning of Electrical Plant and Associated Problems

By R. C. H. Richardson. (Monographs on Electrical Engineering, Vol. 5.) Pp. xvi+363. (London: Chapman and Hall, Ltd., 1938.) 21*s.* net.

ENGINEERS on the whole do not exhibit reticence when recounting difficulties they may have experienced during the commissioning of electrical machinery and plant; but when it comes to publishing such an account, even if time and circumstances permit, the greater the diversity and interest of these experiences the less are they likely to appear in print. It is not surprising that this dearth of literature leads to expectations being aroused, perhaps unduly, if at last what appears to be a record of personal experiences is published.

The book under review gives rise to a reaction which is one of disappointment, for it is distinctly lacking both as regards personal appeal and the recording of instances of the surmounting of 'teething troubles'. In the first place, someone ought to have persuaded the author to discard elementary theory, such as the derivation of the equivalent circuit of a transformer or the elementary theory of vectors, which is to be found in so many existing text-books, and utilize the space thus gained for more meaty matter. Not a few cases of trouble from 'noise' have been encountered when commissioning transformers; yet, in this book, noise does not figure in the index or in the text. The vibration and noise of machinery, it is true, are mentioned on p. 84, but methods of measurement, treatment or cure are not described.

Mathematical treatment has been avoided, but at a price, for instead of being an advanced treatise the book is largely descriptive though lacking photographic illustrations. The text is supported by numerous line diagrams and there is a short bibliography, but it is considered that the list of books given is totally inadequate. Such a serious trouble as that of 'hunting' is not dealt with in the section on alternators and is not referred to in the bibliography.

In favour of the book it may be said that it would serve to guide a reader to the many matters which he may have to study deeply if he is to have confidence in commissioning machinery and plant.

Psychology, Psychotherapy and Evangelicalism

By Prof. J. G. McKenzie. Pp. xiii+238. (London: George Allen and Unwin, Ltd., 1940.) 10*s.* 6*d.* net.

PSYCHO-THERAPEUTIC techniques provide new means for a study of the various types of religious experience, and Prof. McKenzie applies them to the study of Evangelicalism. For examining it he has the important qualification of having shared in the evangelical experience himself. Evangelical Christianity has suffered much from the dramatizing tendencies of its exponents; they have laboured to heighten the vividness of the colour scheme, and the result has been that they have presented the world with something fantastic. The actual facts are more sober. Not all evangelicals are of the 'twice-born' type, nor does the root and centre of their religious experience invariably lie in mystical states of consciousness. Anxious to induce in their converts a conviction of sin, evangelical teachers have sought to deepen their sense of guilt. Prof. McKenzie writes at length and with great insight upon this point, making a clear distinction between "the true sense of sin which involves repentance, and the sense of guilt which is always the outcome of repression and must be removed before repentance and forgiveness can take place". He holds that the well-meant attempt to deepen the sense of guilt "not only does damage to the personality but is a hindrance to evangelical Christianity".

In a most interesting section on "The Meaning of Sin", Prof. McKenzie makes a distinction between "two absolutely different types of personality": the "Ego-centred" and the "Object-centred". The former "makes himself his own main purpose", consciously or unconsciously. The popular notion that virtue consists in "the integration of the personality" is not accepted by the author, for "This integration is not a moral process in itself". The quality of the integrated self depends "on what moral principle has integrated it". Prof. McKenzie has a most illuminating section upon forgiveness; and indeed his book as a whole is so full of valuable material that it will repay study not only by psychologists but also by theologians and ministers of religion. J. C. H.

A Pocket Medical Dictionary

Compiled by Lois Oakes, assisted by Thos. B. Davie. Fourth edition. Pp. xx+409. (Edinburgh: E. and S. Livingstone, 1940.) 3*s.* 6*d.* net.

THE distinctive features of this popular little book, the modest price of which makes it specially suitable for medical students and nurses, are the addition of many new words and the deletion of those no longer current, an appendix on first aid, and an anatomical chart of the human body. We have noticed only one serious mistake, namely, "rotheln" (without an *umlaut*) stated to be the same as "measles", while the following words should be inserted in the next edition: "barbiturates", "erysipeloid", "erythema infectiosum", "fourth disease" and "tularæmia".

Diathermie chirurgicale

Par Dr. C. A. Arraud. (Les actualités physiothérapiques, 1: Électrothérapie, 7). Pp. iv+216. (Paris: Gauthier-Villars, 1939.) 50 francs.

THIS clear and concise little work by Dr. C. A. Arraud, assistant in physiotherapy at the Hôtel Dieu, Paris, is divided into two main parts. In the first, which is introductory, the author deals with the historical aspects of surgical diathermy, the various currents employed, and the choice of an apparatus, particularly those of French origin. The second part is concerned with the employment of surgical diathermy in cancer and in disorders of various systems, such as diseases of the skin, gynæcology, urology, diseases of the alimentary system, neurology, respiratory diseases, otorhinolaryngology and ophthalmology.

The Grasses of Mauritius and Rodriguez

By C. E. Hubbard and Dr. R. E. Vaughan. Pp. 128. (Mauritius: Director of Agriculture; London: The Crown Agents for the Colonies, 1940). 4*s*. 6*d*.; 3 rupees.

MAURITIUS and Rodriguez, alas, so far as their native vegetation is concerned, afford sad examples of the results of human activity in developing a country for its economic possibilities. Sugar cane cultivation and plantations of other exotics have changed the face of the islands with the result that, in place of the original forests of indigenous trees, scrubs and thickets now occupy much of the ground not devoted to plantations. In this change the native grasses have naturally suffered, and many exotic ones have been introduced, and, as is so often the case, have tended to oust the native species, so that, except by studying carefully the habitat of a particular species and its distribution in the island, it is by no means easy to say whether a particular genus or species is a native or not. Seven endemic species are known, but they may not now all exist. Interesting particulars of the indigenous grasses are given in the introduction, and full descriptions, with useful figures of some of them, form the bulk of this useful volume. Excellent keys to the tribes and genera precede the descriptions, and notes are given on the economic uses of the native grasses. There is also an account of the structure and classification of grasses with good text-figures, which should enable anyone to become familiar with the structure of the grass flower and the points used in describing and classifying the genera and species.

The preparation of this account is a valuable piece of co-operative work by the field botanist, with an extensive knowledge of the ecological conditions in Mauritius and Rodriguez, and the herbarium botanist, who has made a critical examination of the specimens, and from his extensive knowledge of the world's grasses has been able to determine which may be indigenous and which introduced.

Since it is becoming necessary to convert waste areas, now dominated by scrub, into grazing lands and pastures, an exact knowledge of the grasses which occur in the islands and of their economic value is most desirable.

The authors are to be congratulated in having produced so useful a piece of work, and also the Government of Mauritius for their wisdom in making its preparation possible, both by their encouragement and by a grant towards its publication.

A. W. H.

Elektrische Höchstspannungen

Von Dr. A. Bouwers. (Technische Physik in Einzeldarstellungen, herausgegeben von W. Meissner und G. Holst, Band 1.) Pp. ix+344. (Berlin: Julius Springer, 1939.) 31.20 gold marks.

THIS book is highly recommended to anyone interested in the technique of high-voltage or high-frequency apparatus and testing, or who is seeking a comprehensive outline of current practice in this rapidly developing branch of electrical technology. It is very well illustrated with 239 explanatory diagrams and photographic reproductions of actual apparatus of recent construction. There is a valuable bibliography, containing 324 references, and an excellent index.

The opening sections are devoted to the theory of high-voltage transformers, cascade connexions, high-frequency transformers, coupled circuits and surge generators, with illustrations from American and Continental practice. The Van de Graaff generator, the cyclotron and apparatus for "Der Blitz" are described. Parts 2 and 3 deal with the theory of electric fields, associated with this class of apparatus, and insulating media respectively, and are supported by good illustrations of modern terminal constructions, bushings and condensers. Valve generators of the Marx and other types are described in Part 4, and the remaining two sections of the book outline, in brief, methods and apparatus for measurements, rectifier tubes, auxiliary apparatus, feeder-circuits and their lay-out for radiography. The latter portion of the book rather tails off, so that it cannot be recommended as a treatise for radiographic technology. The printing and general production of the book leaves nothing to be desired, but its price is excessive.

Concise General Astronomy

By the Rev. O. R. Walkey and Dr. H. Subramania Aiyar. Pp. vii+442+8 plates. (Trivandrum: Sridhra Printing House, 1940.) n.p.

A FOREWORD in this book has been written by Sachivottama Sir C. P. Ramaswami Aiyar, Dewan of Travancore and Vice-Chancellor of the University of Travancore. It is claimed in this foreword that the work deals adequately though briefly with the new concepts as to space, time and relativity—a claim which is justified in spite of the fact that mathematical formulæ are practically omitted. Much important up-to-date information has been included in the text, and an excellent index greatly enhances the value of the book. The appendixes and tables—twenty-five altogether—supply a large amount of useful material in a very concise form on various astronomical matters; some of these deal with Hindu astronomy and show how extensive was the Hindu knowledge of the subject. The work will fulfil its author's aim, "to rouse an intelligent interest in the sublime but generally ignored subject of Astronomy".

Hilfsbuch für das Sammeln und Präparieren der niederen Kryptogamen

Von Prof. Dr. Gustav Lindau. Zweite, neubearbeitete Auflage, von Prof. Dr. O. C. Schmidt. Pp. vii+93. (Berlin: Gebrüder Borntraeger, 1938.) 3.60 gold marks.

IN this useful little handbook, now in its second edition, an account is given of the methods to be employed in the collection and preparation, for herbaria and for subsequent examination, of the lower Cryptogams, sections being devoted to the special requirements of terrestrial, freshwater and marine algæ, myxomycetes, fungi, lichens, mosses and liverworts.

A REMARKABLE PAINTED CAVE ON THE ESTATE OF LESCAUX (MONTIGNAC, DORDOGNE)

By PROF. THE ABBÉ HENRI BREUIL

COLLÈGE DE FRANCE

IN mid-September 1940, several young lads of Montignac, MM. Ravitat, Marsal, Quéroy, Cuëncas, and Estrégil, encouraged by a retired schoolmaster of the town, M. Laval, to explore underground passages in the neighbourhood, cleared out a shaft leading vertically from a plateau to the east of the town. This shaft had been filled up to prevent cattle falling in and only a narrow passage led to the bottom, ending in a hollow into which the young explorers slid after having enlarged it. Descending a slope of fallen boulders, they discovered that some of those fallen from the vault of the first hall were decorated with magnificent frescoes which continued down a narrow alley leading out of it. M. Estrégil made several sketches of these, which he showed to M. Laval, who was at first sceptical about them. Whereupon M. Maurice Thaon, a good sportsman and draughtsman, whom I had known since his childhood, and to whom, a few days earlier, I had shown the painted caves of Font-de-Gaume and La Mouthe, at Les Eyzies, was taken to the cave by the youthful discoverers, and brought careful drawings and some tracings to me.

His descriptions convinced me of the exceptional importance of the discovery. I therefore went to Montignac, where M. Laval, M. Parvan, bailiff of the proprietor, Madame la Comtesse Emm. de la Rochefoucault, and various distinguished people received me most kindly. I asked M. D. Peyrony, delegate of the Ministry of Fine Arts, to meet me there, and a three days' study enabled me to send a preliminary report to the Académie.

The cave in its present state consists of an oval entrance hall (20 m. × 10 m.) continuing in a narrow passage. In the second half of the hall and in the passage there are more than eighty paintings, chiefly on blocks fallen from the vault above. In a short gallery to the right, there are fewer ; but this gallery leads to another lofty hall sloping steeply and leading on the left to a corridor with a high nave, shrinking to a slit of a passage, extremely narrow in parts.

Beyond the lofty hall is a well about 10 m. deep leading by a scramble on the opposite side to ascending galleries, as yet almost unexplored. In the high nave, engravings are generally superposed on paintings ; but they are unaccompanied in the tortuous galleries ; their great number and delicacy have prevented us from deciphering them adequately, as yet.

The paintings vary in size from 30 cm. to nearly 5 m. ; they are of different technique, frequently superposed and restored.

(1) A single little hand outlined in red, with its arm, recalls the Aurignacian type of hands.

(2) Fine line drawings in red, of horses and stags.

(3) Bigger red line drawings, wide blotchy lines filled in with splashes here and there, representing a fairly big horse and bison ; there are also some big bulls and stags covered over and swallowed up by other figures.

(4) Small and medium-sized red, black or sepia line drawings, or in a mixture of these tints more or less filled in with rather transparent sepia or red very much stomped spots. Black touches have often been added later, blending and denoting anatomical details or restoring the outline. A great many small horses, often with very heavy coats, and a great many stags, their antlers in twisted perspective, and one bear (?)

(5) Figures in red, medium-sized, softly dappled, being horses and oxen with small horns and slender build.

(6) Black wash combined with dappling, frequently used in restoration, or depicting single analogous animals.

(7) Two ibex, decorated with wide splotchy black bars.

(8) Stag's heads drawn with a fine black line.

(9) Enormous bulls with big horns, the biggest about 5 m. long, drawn in wide black lines, the colour spreading over the legs and horns and part of the head, the field inside the outline sprinkled with big spots, though usually only the head.

There are neither reindeer nor mammoth, and besides the animal figures there are a good many signs ; rectangles barred lengthwise and across ; five-pronged comb-shaped signs, chessboard patterns filled with big squares of flat wash, the colours arranged in varied ways, looking like coats of arms; lances or javelins with a single barb; arrows, feathered on one side.

The foot of the well boasts a more unusual subject; to the left a black rhinoceros walks slowly away; in the centre, drawn in red, a half-conventionalized man is lying beside a javelin and a throwing stick. To the right, a sand-coloured bison outlined in black gazes at him; its entrails seem to be flowing out like a horse ripped open in a bull-fight. It looks like a scene in a prehistoric drama. Near the man a bird is perched on a post.

Though there may be many surprises in store when the engravings are studied, we can state already there are many horses, oxen, bison, two lions, and what seem like straw huts such as those at Altamira.

As regards the age of the engravings and paintings at Lescaux, the following are some suggestions.

In Dordogne, there are such blocks fallen on the hearths found in the Aurignacian levels and during the Perigordian epoch, in the rock shelters of Blanchard and Labattut (Sergeac) discovered by Monsieur Louis Didon. These blocks display big bichrome figures or the last of the black line drawings. This discovery permitted me to date as of pre-Solutrean age a few figures partially hidden under the big polychromes and black shaded paintings of Magdalenian age at Font de Gaume (Les Eyzies), Le Portel (Ariège) and Cabrerets (Lot), all of which have fine painted panels of that age. It is the same in the Cantabrian provinces; the beautiful Magdalenian frescoes of Altamira are obliterated by red line and red wash drawings, between these two black line drawings intrude.

At Cavalanes and La Haza there are only paintings in wide smudgy red lines, but at La Pasiega such paintings obliterate fine line drawings and have black drawings superposed. The stags and oxen of this ancient series have horns in twisted perspective as at Lescaux, and we have already remarked that this curious perspective is always seen in the open air art of the east of Spain from Lerida to Almeria. The only French examples are those in the rock shelter of Labattut (Sergeac) and the two at Portel (Ariège).

The similarity of the stags and oxen at Lescaux and those in the eastern Spanish art is sometimes so great that they become identical. M. Peyrony and I agree that the whole ensemble of Lescaux represents an art earlier than either the Magdalenian or Solutrean, and except in a few instances is attributable to levels later than the typical Aurignacian. As the much regretted Joseph Déchelette called Altamira "the Sixtine Chapel of Magdalenian art", so Lescaux represents with equal splendour that of the far more ancient Perigordian.

SEARCH FOR PETROLEUM IN AUSTRALIA

By H. B. Milner

SIR EDMUND TEALE'S recent observations on oil occurrences in Gippsland, Eastern Victoria (a summary of which appears on p. 27 of this issue), reopen in critical circumstances two fundamental though wider questions: if there exist *commercial* petroleum reserves in the Commonwealth of Australia, where are they and why have they not long since been exploited ? Now, if ever, is surely the time to realize such assets if they are not for ever to remain frozen.

For many years past, indeed, and since before the War of 1914–18, both casual and ordered search for oil pools in this continent have occupied the attention of pioneers, mining engineers, State, Territorial and Commonwealth Government Departments, also leading oil companies. The record is long, interesting, but in results bitterly disappointing. Even so, belief in possibilities still prevails in many quarters, fostered perhaps more by political and economic than by scientific premises. Let us first briefly review geological data.

The relationship of loci of major oilfields of the Eurasian continent to the Alpine geotectonic system is a firmly established and universally recognized fact. To take the relevant segment in terms of petroleum development, follow through Irak, Iran, North-West India, Assam, Burma, Dutch East Indies to New Guinea: these proved fields in disposition themselves trace those great Tertiary earth-movements responsible for their actual oil concentrations to-day. But equally the fundamentally resistant earth masses to the south, namely, Arabia, peninsular India and, be it noted, Australia, played a significant, if passive, part in restricting the influence of this diastrophism, being themselves practically unruffled in the process.

Thus any oil pools existing in Australia must at least lack the Alpine *cachet*, surely a most serious disadvantage in that part of the globe which even the pernicious habit of wishful thinking cannot entirely overlook. In point of fact, structures impressed on these relatively static earth-masses tend to be epeirogenic and inimical to oil accumulation, even if the requisite mother-substance of petroleum is present in otherwise suitable sediments: witness the Tertiary deposits of Gippsland, almost entirely undisturbed in the sense we understand Iranian or Indo-Burman folding. Although this is all uninspiring re-statement of fact, it is surprising how often and how persistently it has been and still is disregarded.

Frankly, we must recognize that a large part of Australian territory is geologically unfavourable to localized petroleum segregation, especially in West, South Australia and Northern Territory. A fundamental Archæan and Proterozoic complex, counterpart of peninsular India, South Africa and Madagascar, constitutes not only the foundation but also much of the surface geology of this continent. Widespread developments of Palæozoic sediments sterile of oil, masses of Mesozoic epicontinental deposits, relatively undisturbed Tertiary rocks often obscured by thick Quaternary drift, a not inconsiderable development of oil shale in certain regions and an almost total absence of surface indications of petroleum throughout the continent, are basic factors to be contended with in any assessment of oil possibilities.

Even those districts offering some degree of encouragement in the past, for example, Central and Southern Queensland, Victoria, the Victoria – South Australia borderland and some tracts in Western Australia, if pertinently reviewed in proper perspective, fail, at least in my opinion, to raise much enthusiasm either now or for the future.

In Queensland, at Longreach, several boreholes put down for artesian water encountered hydrocarbon gases, small oil flows and mineral wax. Wells in the Permian at Hutton Creek and Arcadia found gas, though often supercharged with carbon dioxide. Work has recently been resumed at these places and deep tests have proved 'wet' gas. Natural gas at Roma, Southern Queensland, has been known for forty years or more, and associated light oil distillates have been refined and marketed on and off since 1927. More recent drilling at Mount Basset near Roma revealed only traces of oil and gas. So in spite of widespread exploration in this area over a protracted period of time, no main oil pool has yet been located, and subsurface conditions, so far as they are known at present, do not give grounds for hope that anything spectacular lies ahead of further developments, however extensive and far flung they may be.

Tests in New South Wales, for example, Kulnura and Mulgoa, produced negative results. Search has been carried out in the Hunter River Coal Basin, also in the extensive Mesozoic deposits of south-east Queensland and north-east New South Wales, again inconclusively. It would appear that the 'oil shales' (boghead) of the Coal Measures in this State provide a clue to prevailing hydrocarbon conditions, and petroleum, if present, is nothing more than an elusive, sporadic trickle. In the former connexion it should be mentioned that intensive development of the established oil-shale field at Glen Davis, Newnes, is, according to reports received early this year, proceeding on the basis of anticipated production of 10 million gallons of shale-oil per annum, believed capable of expansion to 30 million gallons if adequate Federal subsidy is forthcoming. If such development fulfils early hopes, then this source of fuel must necessarily be of the greatest possible importance to the Commonwealth in present circumstances, especially for the Navy and in the general scheme of national defence.

Eastern Victoria boasts the only producing oil wells in the Commonwealth, at Lakes Entrance, Gippsland district. Since discovery in 1924, an emulsified oil has been obtained from which in latter years an *annual* production of some 25,000 gallons (!) has been recovered. Association of oil with prolific artesian water is scarcely a healthy sign, although the Imray borehole indicated that oil and water sands were separated. The trouble with Lakes Entrance is that there is no natural pressure to cause flow of oil to the wells when the sands are penetrated; hence commercial production is impracticable either by drilling or pumping. It would appear to be equally impracticable to use the underlying water to flush out the oil. Some system of air repressuring might be tried as suggested by Sir Edmund Teale, but to do this satisfactorily means effective plugging of all producing and shut-down wells, to say nothing of a financial outlay of considerable dimensions.

Although it has been reported that some 150 million gallons of oil are available here, even if economically recovered, no petrol or fractions lighter than lubricating oil could apparently be refined from it. Is such an enterprise worth while even as a war-time measure? If there is a doubt about it now, how much more hazardous would be the project in peace-time. Sir Edmund makes out a good case for speedy consideration and action by Government and other interests concerned, but even so the chances of success are not impressive. Apart from Lakes Entrance, recent drilling activities at Lake Boga, Portland, and at Nelson came to naught, while another enterprise at Dutson showed no sign of oil or gas.

In the South Australia – Victoria borderland country, the Tertiary deposits are alleged to contain some oil, but it is probably widely dispersed. Oil seepages reported from Glenelg River when followed up led to nothing. Prospecting carried out in this region seems to have been inspired by a widespread occurrence of bitumen along the whole southern coast of the continent, quite probably washed up by prevalent Antarctic tides.

In the Kimberley region of North-West Australia trials for oil were made at Nerrima, south-east of Broome, in 1939, but no oil or gas shows of consequence were encountered. Again, in his report on petroleum prospects of the Kimberley district of Western Australia and Northern Territory, made more than sixteen years ago, Dr. A. Wade wrote: ". . . the area could not have been less favourable from the point of view of prospecting for, or for the finding of, petroleum supplies. It is more suited to the prospector for gold and other minerals . . ." One cannot escape the feeling that this last remark applies to a far larger part of the continent than many people realize.

THE RUBBER RESEARCH INSTITUTE OF MALAYA

BY SIR GEOFFREY EVANS, C.I.E.,
ROYAL BOTANIC GARDENS, KEW

ABOUT ninety per cent of the rubber in the world is manufactured from the latex of the tropical tree *Hevea Braziliensis*, a native of the Amazon region of South America, but now cultivated on a plantation scale in Malaya, the Netherland Indies and Ceylon, which areas produce practically all the rubber of commerce. The story of how Sir Henry Wickham managed to secure seeds of this wild tree from Brazil in 1876, and its subsequent transfer, via Kew, to the Peredeniya Gardens in Ceylon, and thence to Malaya and the East Indies, is a fascinating one. Some of the original trees are still growing at Peredeniya. From these small beginnings, the vast plantations of the Far East have their inception. In Malaya alone the area under rubber amounted to more than three and a quarter million acres in 1937, and the exports to nearly 500,000 tons, valued at nearly 350 million Straits Settlement dollars.

The industry made enormous growth at the start; but like so many other plantation industries, it had, at a later stage, to face obstacles in the shape of lower prices and fluctuating markets following periods of over-production. The earlier planters merely cleared the forests and planted rubber and were content to collect the produce without devoting much attention to the methods of cultivation. In this respect rubber presented no difference from many other tropical plantation crops. A period of boom prices would result in the wholesale planting of areas, irrespective of soil and climatic conditions, but subsequent slumps, combined with acute competition, brought home to those interested in the industry the vital need for research and for control in the output. With the ramifications of the rubber restriction proceedings we are not concerned; but the progress of the research work is a subject worthy of more than passing note, in view of the thorough manner in which the need has been met.

In the years immediately succeeding the War of 1914–18, the pros and cons of the matter were thoroughly thrashed out by those vitally interested in the commodity, both in London and in Malaya, and their views crystallized into the idea that a research station was needed, which would be in a position to tackle the various problems that beset the industry. The problems were many. There was first the system of cultivation. It had been considered from the first that clean weeding was essential to the successful growth of the rubber tree; but tentative experiments made by the Agricultural Department had indicated that this system was not necessarily the best, and that it resulted in the loss of much soil through erosion. Sir Lewis Fermor, in a recent report on the mining industry of Malaya, hinted that possibly as much erosion had been caused by rubber planting as by tin mining operations, which had always hitherto been blamed. Nowadays one hastens to explain this is not the case, as cover crops are the usual practice on rubber estates and clean weeding has been abandoned, and with it much erosion has been checked.

The Rubber Research Institute of Malaya was at length organized and started work in September 1926, and, after the usual teething troubles which seem to be inevitable with institutions of this nature, it can now be considered to have fairly got into its stride. A study of the annual report for 1939 gives full indication of this, and a perusal of the 277 pages will convince readers of the thorough way in which diverse and complex problems are being investigated.

The Institute is situated near Kuala Lumpur on a suitable site and is well equipped with a competent staff and excellent laboratories and land for experimental work. The scientific work is organized into several divisions dealing with botanical, soils and fertilizers, technological and pathological problems ; there are also an experimental station of 1,850 acres at which work on cultural matters is investigated and experimental field plots laid out. In addition, there is much advisory work which preserves contact with the planters throughout the area. Close co-operation is maintained with the Rubber Research Scheme of Ceylon, with the London Advisory Committee, and other scientific institutions in Great Britain, and with the British Rubber Producers Research Association. This latter body is a part of the International Rubber Research Board, and by this means close liaison has been established with other research workers in Java and elsewhere.

In the Soils Division much has been accomplished in examining the various types of soil that occur in the peninsula with regard to their suitability for rubber growing and in ascertaining the manurial requirement for each type. Erosion problems are being examined, and the various systems of establishing new plantings by the relative methods of no burning versus light or normal burning are being tested. Whilst clean cultivation has now been abandoned, it has been found in practice that the establishment of permanent cover crops is not an easy matter on certain types of soil and are certainly difficult to maintain under mature rubber. Experiments in inoculation and manuring are, therefore, being made to try to get over the difficulty.

Valuable work by the Botanical Division has been done in the provision of improved planting material. The percentage of acreage replanted with higher yielding material is still considerably less than that of Java, as the Netherlands Indies started work of this nature several years before Malaya. Much progress has now been made in selecting high-yielding trees for bud wood, the number of high-yielding clones that have been tested and approved shows annual progress and the demand for the material is greater than the supply. The stage has now been reached when the yield from the present best proved clones is unlikely to be exceeded by selection from further high-yielding trees ; resort is accordingly being made to pollination between high-yielding clones, and some of the seedling clones resulting are stated to be of high promise. Further valuable work by this division is being undertaken in testing different kinds of tapping systems, in the use of growth-promoting substances in the vegetative propagation of Hevea, and in stock-scion relationships. An interesting piece of work from which good results are expected, is in studies of the nutrition of the plant and also the connexion between leaf symptoms and various deficiencies.

The Pathological Division deals with pests and diseases. One of the chief troubles in newly planted areas is the control of root disease. Control of old stumps which are the focal points of the disease seems to be best assured by the use of sodium arsenite. An interesting piece of work is in the testing of nodule bacteria in connexion with the growth of cover crops, such as Pueraria and Centrosema, which, as mentioned above, are not always easy to establish.

The Chemical Division deals mainly in technological problems, in which direction the industry has made important advances in recent years. A new type of smoke house for crêpe rubber designed by the Institute has become popular and has been built on a number of estates. Other problems are connected with the shipment of latex, for rubber is now being transported in this form in increasing quantities in recent years. For this purpose the latex has to be concentrated. The concentrating of the latex, the preventing of discoloration, and the use of certain reagents for concentrating, are all matters under investigation. Incidentally, it is interesting to note that it has been found that different clones produce rubbers of different consistencies, some, for example, producing rubber of an abnormal softness.

It has only been possible to touch the fringe of the research work that is described in the annual report, but it is obvious that much work is being conducted on sound lines, which augurs well for the future of the industry. Plantation rubber will probably have to face competition from the artificial product in the future, for the effect of the War has been to stimulate research in the manufacture of rubber substitutes by synthetic methods, particularly in those countries which are unable to get natural rubber on account of blockade. It is satisfactory, therefore, to feel that those interested in the plantation industry, which is of such vital importance to Malaya and Ceylon, have taken steps to apply research methods with the object of raising the output per acre and reducing costs, and at the same time have realized the importance of regulating output so that the product may be made available to the whole world, when conditions again become normal, at a reasonable and stabilized price. By such methods the industry will be in the best position to meet any outside competition in the future.

SCIENTIFIC CENTENARIES IN 1941

By Engineer Captain Edgar C. Smith, O.B.E., R.N.

AMONG the men of science whose centenaries occur this year, one stands out above all the others as a great reformer. This is Paracelsus, who died at Salzburg on September 24, 1541, four centuries ago. Born in Switzerland in 1493, he was a contemporary of Copernicus and Luther. In Dr. Seelig's "Medicine, an Historical Outline", Paracelsus is spoken of as "a man of extraordinary power, forceful character, untrammelled thought and ingenious medical instinct". His wanderings, his quarrels and his constant warring against dogma made him known throughout the universities of Europe, and interest in his activities has continued down to the present time. In NATURE of January 18, 1894, there was a note to the effect that the library of Dr. Schubert, of Frankfort-on-Main, contained no fewer than 194 editions of the works of Paracelsus, and 548 books dealing partly or chiefly with him. One of the latest lives of Paracelsus is that of Prof. J. M. Stillman, which was reviewed in these columns on August 12, 1922, by Sir Edward Thorpe.

Paracelsus lived at a time when the study of botany was attracting considerable attention. Medicine and botany went hand in hand, and this led to the foundation of botanic gardens. Those at Padua, Montpellier, Leyden and Leipzig were all founded in the sixteenth century, and that in Paris, now the Jardin des Plantes, in the early part of the seventeenth century. The inauguration of this garden was due to the French physician Gui de la Brosse, who died in 1641. He was a physician to Louis XIII. He bought a piece of land on which refuse had collected and there established in 1626 a Jardin Royal des Plantes Médicinales, of which he became the first superintendent. He collected plants from many parts of the world; in 1636 he made a catalogue of 2,000 specimens, and had upwards of 400 plates engraved. At his death these were disposed of to a brazier, but Fagon, the nephew of Brosse, was able to save about fifty of them from destruction. Nearly all Brosse's writings were about the garden and its plants.

The year 1641 also saw the death of Jeremiah Horrocks, the young Lancashire clergyman and astronomer, the first individual to witness a transit of the planet Venus.

Astronomy of the following century is represented by François de Plantade, of Montpellier, who died on August 25, 1741. With his countryman Clapies, Plantade observed the total eclipse of the sun of May 12, 1706, the first total eclipse of which the accounts, says Grant, have any pretensions to fullness or precision. That same year Plantade assisted in founding the Academy of Sciences at Montpellier. Born in 1670, he died suddenly at the age of seventy when climbing the Pic du Midi to carry out geodetical measurements.

Other men of science who died in 1741 were Ambrose Godfrey, who for many years assisted Boyle in his experiments; George Martine (1702-41), the St. Andrews physician, who in 1740 published an essay on the "Natural and Experimental History of the various degrees of Heat in Bodies", and the Danish navigator, Vitus Behring. who after serving in the navy of Peter the Great, spent several years exploring Siberia, its coasts and seas, and who perished on Behring Island on December 19, 1741.

The great explorers of the eighteenth century include also Jean François de Galaup, Comte de La Pérouse, who was born on August 22, 1741. After seeing active service in the Navy, he was given command, when forty-four years old, of an expedition to the coasts of the Pacific. In 1788 he sailed from Botany Bay, and no trace of him was found until 1826, when it was discovered that his ships had been wrecked on a coral-reef off Vanikoro, north of the New Hebrides. While La Pérouse was still serving in the French Navy, his fellow countryman Alexis-Marie Rochon (1741-1817), optician and astronomer to the Marine, was visiting many places in the Indian Ocean. With Leroy he was made keeper of a cabinet of nautical instruments at Brest. His attainments gained him a seat in 1795 in the newly founded National Institute, and when he died his place was taken by Fourier. Another well-known French man of science born in 1741 was the geologist Barthélemy Faujas de Saint-Fond (1741-1819). He held a chair in the Museum at Paris, and he was among the first to bring forward conclusive evidence of the igneous origin of basalt. His work "On the Extinct Volcanoes of Vivarais and Velay" was published in 1784. About this time he visited Great Britain and was hospitably entertained by Sir Joseph Banks and others. He attended a dinner of the Royal Society Club, of which he wrote, "Brandy, rum and some other strong liquors closed this philosophical banquet, which terminated at half-past seven, as there was to be a meeting of the Royal Society at eight o'clock. . . . I repaired to the Society along with

Sir Joseph Banks, Mr. Cavendish, Dr. Maskelyne, Mr. Aubert and Sir H. Englefield. We were all pretty much enlivened, but our gaiety was decorous." At Windsor, Faujas was startled to find Miss Caroline Herschel assisting her brother in recording observations.

Three Englishmen of note who were born in 1741 were Dr. William Withering, F.R.S. (1741–1799), physician, botanist and mineralogist, of Birmingham, friend of Watt, Priestley and Boulton; Joseph Huddart, F.R.S. (1741–1816), nautical surveyor and chart maker, who made a fortune out of his rope-making machine patented in 1799, and the Cornish clergyman and astronomer, the Rev. Malachy Hitchins (1741–1809). Though he began life as a miner, Hitchins was enabled through his wife to go to Oxford, and in 1767 Maskelyne found him a post at Greenwich Observatory as a computor. He made calculations for the "Nautical Almanac" from 1768 until his death at St. Hilary Vicarage, Cornwall, in 1809: "The reputation which the Nautical Almanac obtained was largely due to his care. . . ."

The names of men of science who died a century ago include those of the famous Swiss naturalist, Augustus Pyramus De Candolle, of Geneva, whose "two-fold enthusiasm was to increase the knowledge and advance the welfare of the human race", and the French entomologist, Jean Victor Audouin, a son-in-law of Alexandre Brongniart, the successor of Latreille at the Muséum d'histoire naturelle, a collaborator with Milne-Edwards and the first president of the French Entomological Society. Another French naturalist who died in 1841 was Jean François D'Aubuisson de Voisins (1769–1841), the geologist, who was the favourite pupil of Werner at Freiburg, but who abandoned Werner's views after he had visited the volcanic region of Auvergne. The same year saw the death of Felix Savart (1791–1841), the physicist who succeeded to Ampère's chair in the Collège de France; of the famous British surgeon, Sir Astley Paston Cooper, who is buried beneath the chapel of Guy's Hospital and whose statue is in St. Paul's Cathedral; of Dr. George Birkbeck (1776–1841), the pioneer of technical education, whose best-known memorial is Birkbeck College, London, and of the two mathematicians, Olinthus Gilbert Gregory (1774–1841) and George Green (1793–1841). Gregory, who was one of the projectors of the University of London, taught for many years at the Royal Military Academy, Woolwich, and was known both as a writer of text-books and as experimenter, while Green is remembered principally for his "Essay on the Application of Mathematical Analysis to the Theories of Electricity and Magnetism", in which he first applied the term "potential" to these branches of science. Green was largely self-taught; and he did not study at Cambridge until he was forty years of age, five years after his essay was published. He was only forty-seven when he died.

Of the many men of science born in 1841, one of the most eminent was the French physicist Marie-Alfred Cornu, For. Mem. R.S. (1841–1902), for many years professor of physics at the École Polytechnique, and in 1896 president of the Paris Academy of Sciences. After his death in 1902, Silvanus Thompson wrote of him in NATURE as a man who had won universal esteem: "A true follower of the great traditions of France in the pursuit of science and a passionate follower of Arago, Biot, Fresnel and Fizeau, he was in his own person much more than this. He was the ideal of a well-equipped well-balanced intellectual leader in scientific thought."

Science in Italy last century is represented in the records by Antonio Pacinotti (1841–1912), who, as a youth serving in the Garibaldean Wars, pondered over the construction of his ring armature dynamo, for the invention of which he is remembered, while science in Switzerland is represented by the Lausanne anatomist and physiologist, François Alphonse Forel (1841–1912), who made a life-long study of the Lake of Geneva, and whom Chrystal called "the Faraday of Seiches".

Centenaries of astronomers of note, professional or amateur, are numerous, for 1841 saw the birth of Herman Vogel (1841–1907), director of the astrophysical laboratory at Potsdam; of Friedrich Engelmann (1841–88), of Leipzig, who published Bessel's collected works; of Theodor von Oppolzer (1841–86), of Vienna; and of Hugo Gylden (1841–96) of Stockholm, both known especially as eminent teachers. Three British astronomers born in the same year are Andrew Ainslie Common (1841–1903), an engineer who became known for his construction of silver-on-glass mirrors; W. E. Crossley (1841–1905), a carpet manufacturer, who at Halifax installed a telescope having one of Common's mirrors which he afterwards gave to the Lick Observatory; and G. F. Chambers (1841–1915), a lawyer, who was the author of an excellent "Handbook of Descriptive Astronomy" which passed through several editions.

To complete this survey, brief mention may be made of several workers in other fields of science. Karl August Lossen (1841–93), a member of the Prussian Geological Survey, was spoken of as the founder of dynamic metamorphism; Edouard François Dupont (1841–1911), another geologist, was the honorary director of the Royal Museum of Natural History at Brussels, and William Topley, F.R.S. (1841–94), who did notable work on the Geological Survey of Great Britain and served as president of the Geologists' Association. Topley began his work on the Survey with Clement le Neve Foster, F.R.S. (1841–1904), who had studied at Freiburg, and in 1890 succeeded Sir Warington Smyth as professor of mining at the Royal School of Mines. In 1903 Foster was knighted. The Irish chemist, Cornelius O'Sullivan (1841–1907), and the English chemist, Walter Flight (1841–85), both owed much to their contact with Hofmann, to whom they became assistants after his return to Berlin. Both were fellows of the Royal Society, but while O'Sullivan's researches were connected with the chemistry of brewing, Flight's investigations led him to the study of the mineralogical constitution of meteorites, his work being done in a laboratory at the British Museum, where he held a post. Of the engineers born in 1841, John Donaldson (1841–99) and George Wallace Melville (1841–1912) were connected with marine engineering. Donaldson was a pupil under Rankine at Glasgow; in 1872 he joined Sir John Thornycroft at Chiswick, and was associated with the development of high-speed torpedo boats and torpedo-boat destroyers. Melville held the high office of engineer-in-chief of the United States Navy for sixteen years, during which period the American fleet grew from an almost negligible force to one of the most powerful.

OBITUARIES

Dr. J. W. Blagden

Dr. J. W. Blagden died on November 28 at his home in Loughton, Essex, in his sixty-seventh year. He came from a scientific family, and was educated at Dulwich and Emmanuel College, and took an honours degree in natural science in 1895. Proceeding to Würzburg, he worked under Häntzsch, obtained his Ph.D., and after a period as senior demonstrator in electro-chemistry at Darmstadt, entered industry with C. F. Böhringer und Söhne as research chemist and departmental manager. He worked on electrolytic oxidations and reductions, and later became interested in the then new field of catalytic hydrogenations. In this, particularly in its applications to industry, he was one of the pioneer workers. The outbreak of war in 1914 put an end to his work in Germany. During the period of hostilities he was an internee at Ruhleben, where as the leader of a group he endeavoured to continue scientific work, an effort typical of a man who refused to be dismayed by difficulties. At the end of the war he returned to England and sought an opportunity to continue his work on catalysts. He joined Messrs. Howards and Sons, Ltd., in 1919 and undertook the organization and direction of a newly formed Research Department. The range of new products manufactured by the firm during the last twenty years is a tribute to the energy and skill with which he pursued the task. In 1929 he was elected a director of the Company.

Blagden was a fellow of the Institute of Chemistry and the Chemical Society, and a member of the Society of Chemical Industry. He served on a number of Committees, among which may be mentioned the Pharmacopœia Commission, the Essential Oils Committee of the Imperial Institute, Chemical Committees of the British Standards Institution and the Patents Committee of the Association of British Chemical Manufacturers.

He had little desire or time for publication, and apart from a few relatively minor papers the record of his work exists in patents and in the technical achievements of the laboratory under his direction.

Dr. Blagden was always accessible to members of his staff, and devoted much of his time to their encouragement and welfare. He felt that industry owed a debt to the universities, and was pleased to acknowledge this by both material and technical assistance whenever possible.

Dr. C. W. Saleeby

Dr. C. W. Saleeby, who died on December 9, aged sixty-six, was a popular lecturer and writer, able to put forward the views he furthered in simple direct language illuminated by apt and telling phrases. He was in particular an exponent of eugenics, in my opinion a lost cause, for the British people cannot be persuaded, and are not stimulated by family allowances by Government, to have enough children to maintain the vigour of the nation after the War. There is great doubt, too, whether eugenics, except in the case of a few rare inherited disabilities, is of any value.

A far more valuable field of Saleeby's propaganda was that of sunlight and open air as givers and restorers of health. He founded the Sunlight League, and its continuance depended mainly upon him. In the *Journal* of this League were well advocated the views he held so strongly. His own dwelling in London was contrived to secure all the benefit possible from sunlight. In his lectures he made much of Rollier's great successes in treatment of tuberculosis at the Leysin Sanatoria and the open air school run there as a prevention of disease for delicate children. In doing so Saleeby did not seem to be aware of the pioneer work of that great surgeon Oscar Bernhard at St. Moritz, who inspired the work of Rollier and whose surgical methods of wound treatment by sun and open air are of great value to-day. With the death of Saleeby an enthusiastic popular teacher has passed away.

Leonard Hill.

NEWS AND VIEWS

President Roosevelt and United Democracy

IN his 'fireside talk' on December 29, President Roosevelt reached the highest point he has yet attained in his career as statesman and a great leader of democracy. No less than the successes of allied arms in the field, it holds out a promise of ultimate victory and marks a substantial stage in progress towards a 'new order' of democratic unity. As he had elected national security rather than war as his topic, his statement was addressed primarily to the people of the United States; but in order that he should place the situation as it affects their country fairly and squarely before them, he was bound by the logic of present realities to show how the forces of aggression embodied in the Axis Powers form a threat to the Americas as a whole, and in aiming at a world domination were bent upon the destruction everywhere of that freedom which is of the essence of democracy. By the cogent argument of the facts of recent history in the action of "a gang of outlaws" against weaker neighbouring peoples, and the inevitable consequences which would follow their success in Europe, he showed that American civilization and American independence "had never before, since Jamestown and Plymouth Rock," been in such danger.

"The Nazis," Mr. Roosevelt went on to point out, "can never reconcile themselves to a democratic world. The Axis proclaims there can be no ultimate peace between their philosophy and ours." The grave warning addressed to the people of Eire indicated that, in the opinion of the President, no less than of others more intimately involved, no reliance is to be placed upon the protection of a neutrality such as that on which Eire takes its stand. To the threat to the Americas the armed forces of Great Britain and those soldiers of its allies who have escaped alone oppose a barrier. Hence it behoves America, in President Roosevelt's words, to become the arsenal of the democracies, and to spare no effort, short of an expeditionary force, to support them. So from the President's exhortation to the American people there emerges a pattern—it might almost seem a prophecy—of a world in which stand united all peoples who hold fast to the democratic ideal, with Great Britain and the United States in the forefront. They stand, and will continue to stand, united in defence of those ideals, freedom, justice and tolerance, everywhere and at all times against aggression and exploitation.

The Fire of London

ON December 29, after four months of vicious, though unsuccessful, attempts to destroy the spirit of London, the Nazis attempted to destroy her heart by fire from the air. Those of us who experienced the wanton assault need no further proof that it was a deliberate attempt to fire one of the most vulnerable points in the world, although no targets of military value were attacked. It may be that the attack was not necessarily one of desperation (as suggested in some quarters), but rather an integral part of the Nazi war effort to destroy anything symbolical of the democratic ideal and tradition. If so, then it has proved a dismal failure; London has withstood its ordeal by fire. It is true that some irreparable material damage has been done. Guildhall is a blackened shell; eight Wren churches have been wrecked; the Central Criminal Court has been damaged; the house in Gough Square, Fleet Street, where Dr. Johnson compiled his dictionary has been burnt out; Goldsmiths' College, which is incorporated in the University of London, was destroyed; and so on. The night was awesome—a clear demonstration of the senseless ferocity of aerial warfare as conceived by the Nazis.

But St. Paul's Cathedral, symbol of the faith of many Britons, stood out as a challenge and an inspiration. It has withstood previous attacks, though that of Sunday, December 29 must inevitably rank high among the many barbarous, though futile, attempts by the German High Command to crush the armies of freedom. History is being writ large; but more important at present is it that here we have further proof, if such is needed, that we are fighting, and must overcome, evil things. Nobody but another Nazi could support such 'strategy', which is eloquent of the very philosophy of totalitarianism, emphasizing as it does, among other things, the total destruction of all that democracy stands for, material and moral. Lovers of freedom, whether in the fighting services, defence services, office, field, library or laboratory, must collaborate wholeheartedly and give of their best, and thus become effective defenders of freedom.

British Museum (Natural History): Air Raid Damage

A NUMBER of bombs, both high explosive and incendiary, have fallen on the Museum premises, and serious fires have occurred in the General Herbarium and the Shell Gallery. Considerable damage was done to the botanical collections, but it will be impossible for some time to arrive at any final conclusion as to the extent of this, since so much depends on the degree of success achieved in the work of salvage and reparation which is still in progress. The greater part of the damage was done by water, and time alone can show how far this is irreparable.

The Shell Gallery was fortunately almost empty when the fire took place, and the damage to the collections was inconsiderable, though the roof of the Gallery was destroyed and a number of show cases were ruined. Some damage has been done by water in other parts of the Museum, but this is believed to be not very great. A vast number of windows and skylights have been broken, and there has been minor damage to the structure and to furniture in various parts of the building. The fossil tree which stood in the Museum grounds has been knocked down and broken but is capable of being repaired and re-erected.

Moss in War-time Medical Dressings

THE position in the War of 1914–18, when the acute shortage of cotton-wool necessitated the widespread use of Sphagnum moss as an absorbent dressing for field wounds, has been anticipated in the present efforts to recommend reserves of this material properly collected and suitably prepared (*Lancet*, Dec. 14, p. 753). During 1914–18, when the War Office officially sanctioned the use of bog-moss and itself ordered considerable supplies from Dublin and Edinburgh War Dressings Supply Centres, Colonel C. W. Cathcart, of the Edinburgh Royal Infirmary, investigated its properties in comparison with other cheap and easily available absorbants and deodorants like pinewood sawdust and peat moss litter and showed its considerable advantage, even over ordinary cotton-wool (*Brit. Med. J.*, July 24, 1915).

The history of Sphagnum as a wound dressing is, however, older than the War of 1914–18. The earliest record is given in Joyce's "History of Ireland", when it was described as used for a wound dressing on the battlefield in the battle of Clonturf in 1014. The first use in medical science was at Kiel, in Germany, last century, when a workman who had lacerated his forearm had it wrapped in peat moss, and he was sent down to Kiel, where he arrived ten days later, and, to the surprise of the medical authorities on removing the moss, the wound had healed most satisfactorily (Neuber : "Erfahrungen über Iodoform under Torf-Verbande", *Arch. klin.-Chir.*, **27**, 757 ; 1882). The first recommendation for its use by the British during the War of 1914-18 was apparently Prof. J. Bailey Balfour's letter to the *Scotsman* of November 17, 1914, although the pioneer work in medical circles was that of Col. Cathcart. The Canadians and Americans in the later stages of the War were preparing considerable supplies of these dressings for their own troops in the field. In 1916 the Irish material prepared at Dublin reached an output of 20,000 dressings a month, 5,000 of which went to the War Office and the rest to eighty hospitals. The Edinburgh station was supplying 2,000 dressings a week for military use without charge.

British Drug Plants

THE wholesale cultivation of drug-producing plants in Great Britain is being encouraged by the Pharmaceutical Society and the Ministry of Agriculture to meet the deficiency of Continental imports, and a medical correspondent in the *Lancet* of December 7 points out the dangerous position arising from the prohibitively high prices and the acute shortage of necessary drugs. A survey by the *Chemist and Druggist* of the present conditions on the nine big commercial drug-plant farms in Great Britain reports a fairly good harvest this past season, but considerable extensions will be required to meet the needs of the manufacturing chemists in 1941. The chief plants required, and suitable for wholesale cultivation as field crops, are deadly nightshade (*Atropa belladonna*), thorn-apple (*Datura stramonium*), henbane (*Hyoscyamus niger*), monkshood (*Aconitum napellus*), foxglove (*Digitalis purpurea*), hemlock (*Conium maculatum*), white horehound (*Marrubium vulgare*), skull-cap (*Scutellaria galericulata*), male fern (*Lastrea Filix-mas*), mother-wort (*Leonurus cardiaca*), chamomile (*Anthemis tinctoria*), wormwood (*Artemisia absinthemum*), squirting cucumber (*Ecballium elaterium*), opium poppy (*Papaver somniferum*), and valerian (*Valeriana officinalis*).

Fortunately, the Ministry of Agriculture's handbook on the subject is an up-to-date work with the experience of the War of 1914–18 ; but, in addition to cultivating the herb crops, accurate methods of early harvesting and early and slow drying are necessary if the full chemical resources of the plants are to be available. It may also be necessary to cultivate herbs of the Labiates, like lavender (*Lavendula vera*), rosemary (*Rosmarinus officinalis*) and wound-wort (*Stachys betonica*), and some Umbellifers, like angelica (*Angelica archangelica*), for their essential oils for the perfumery and essential oil trade. Although the position regarding organic dyes is much better than in the War of 1914–18, the return to cultivation of woad (*Isatis tinctoria*) and other dye-producing plants is envisaged.

Palæolithic Paintings in the Dordogne

IN the enthusiasm of fresh discovery, archæologists at times are apt to overstress the importance of their finds. No reservation is necessary in appreciating the outstanding character of the remarkable discovery of the cave and paintings of palæolithic age at Lescaux in the Dordogne valley, recorded by the Abbé Breuil in another column of this issue of NATURE (see p. 11). Although at the time of writing examination of the cave had proceeded no further than would warrant a preliminary report, sufficient of its nature had already been revealed to justify the conclusion in the opinion of the Abbé Breuil that the discovery is of exceptional importance. To quote his own words "as . . . Déchelette called Altamira 'the Sixtine Chapel of Magdalenian art', so Lescaux represents with equal splendour that of the far more ancient Perigordian". In this remarkable cave with its high central hall and galleries, the latter for the most part still unexplored, are more than eighty paintings, chiefly on blocks fallen from the roof, as well as engravings—in the hall superposed upon the paintings, in the galleries unaccompanied—which it has not yet been possible to examine adequately on account of their delicacy.

In the paintings, the Abbé Breuil distinguishes according to character and technique nine divisions or classes, each depicting characteristically animals or parts of animals, as well as rectangles, comb-shaped signs and other conventional forms. Reindeer and mammoth notably are absent, while "more unusual" is a composition in which black rhinoceros, bison, and a recumbent human form appear—possibly "a prehistoric drama", and if so a valuable piece of evidence bearing upon the nature of palæolithic belief and ritual. From this evidence the Abbé Breuil draws certain tentative conclusions as regards the age of the engravings and paintings. The stags and oxen show a truly remarkable and unique

R277

similarity with those of the eastern Spanish palæolithic art, where also is found a twisted perspective in depicting horns of stags and oxen, which appears at Lescaux. From this and other comparisons, the important inference is drawn that the paintings of Lescaux are earlier than both Magdalenian and Solutrean, but later than typical Aurignacian. They represent the phase of Upper Palæolithic culture, but recently differentiated and known as "Perigordian".

Prof. Ernest O. Lawrence: Duddell Medallist

THE formal presentation of the seventeenth Duddell Medal of the Physical Society to Prof. E. O. Lawrence, the award of which was announced in NATURE of June 1, p. 852, was made at a dinner of the American Physical Society in Philadelphia on December 27 by Mr. Neville Butler, First Counsellor to the British Embassy and H.M. Chargé d'Affaires *ad interim* in Washington—it had been the late Lord Lothian's intention to present the medal. At a luncheon held by the Physical Society in London on the same day, an interesting word picture of Prof. Lawrence was given by his friend and former pupil, Dr. W. B. Mann. Dr. Mann first referred briefly to the development of the Berkeley cyclotrons, from the 4-inch instrument in 1930 (when Lawrence, at the age of twenty-nine, had recently been appointed professor of physics in the University of California), to the 37-inch (85-ton) and 60-inch (220-ton) cyclotrons and the projected giant cyclotron of some 4,900 tons. He then described the team work of the Radiation laboratory at Berkeley and recalled many incidents to show the outstanding qualities of its distinguished chief—his deep, innate *sense* of physics, his skill in finding the causes of breakdowns, his large share in making the subsequent readjustments until perfect running was again effected, his boisterous and irrepressible enthusiasm away from work (such as on a ski-trip or in his motor-cruiser on San Francisco Bay), and his complete selflessness. Prof. Birge had quoted Lawrence's first remark on being informed of the award to him of the Nobel Prize for Physics in 1939: "It goes without saying that it is the laboratory that is honoured, and I share the honours with my co-workers past and present." Again, the closing words of Lawrence's response at the presentation of that Prize were: "May I again give expression to a profound feeling of gratitude and appreciation for this great honour, which I share with the university and with all those outside who have contributed to make our work possible and, above all, with my valued colleagues and co-workers both past and present." An article based upon Dr. Mann's address appears in the January issue of the *Proceedings of the Physical Society.*

PROF. E. O. LAWRENCE.

New Cyclotron at Berkeley, California

GOOD progress is being made, according to news received recently from the United States, in the erection of the 184-inch cyclotron at Berkeley, California. The cost of this apparatus, it will be recalled (NATURE, May 18, 1940, p. 776), will be more than £200,000, and is being provided by the Rockefeller Institute. The concrete bed for the steel magnet, containing 1,200 tons of concrete, is finished. The erection of the steelwork is now starting, and is expected to be completed by April next. This will contain 3,700 tons of steel, the overall dimensions being, length 56 feet, width 184 inches, height 30 feet. The upper and lower yokes are to be built of some 36 sheets each of steel, 2 inches thick and 56 feet long, bolted and ultimately to be welded together to withstand earthquake shock. 300 tons of copper in the form of strip, 4 inches wide and ½ inch thick, will be required for the windings. The cyclotron is expected to yield one hundred million electron-volt deuterons in a field of 10 kilogauss, for which the resonance wave-length is 39 metres.

Physiology at Cambridge: Mr. W. Freeman

AT a meeting of the Physiological Society held in Cambridge on December 18, a presentation was made by physiologists trained in the Cambridge school to Mr. William Freeman, the senior laboratory assistant. Mr. Freeman, known to many generations of students as 'John', completed his fiftieth year in the laboratory last October. As biological technician he was closely associated with Langley and Anderson in their work on the autonomic system, but during the past fifty years he has aided no less than four of the secretaries of the Royal Society (Michael Foster, Sir William Hardy, Sir Henry Dale and Prof. A. V. Hill) and three of its presidents (Sir Charles Sherrington, Sir Frederick Gowland Hopkins and Sir Henry Dale). The presentation was made by Sir Henry Dale after congratulatory speeches by Prof. E. D. Adrian and Dr. L. E. Shore.

Tercentenary of Jeremiah Horrocks

ON January 3 occurred the tercentenary of the death of the young Lancashire curate Jeremiah Horrocks, whom Herschel spoke of as the pride and boast of British astronomy. In the fourteenth year of the reign of Charles I, and some twenty years before the foundation of the Royal Society, in the hamlet of Toxteth Park near Liverpool and in the village of Hoole, eight miles south of Preston, Horrocks, with the aid of the tables of Lansberg and the works of Kepler, recalculated the transit of Venus and, on Sunday afternoon, November 24, 1639, in between his church services at Hoole, had the great satisfaction of watching the passage of the planet across the sun's disk. His friend, William Crabtree, also observed the transit from near Manchester, but Horrocks's brother Jonas, at Liverpool, failed to see it owing to clouds. Within fourteen months of his achievement, Horrocks had passed away, being then but twenty-two or twenty-four years of age. He had, however completed his "Venus in Sole Visa".

Though he made his observations at Hoole, Horrocks passed most of his life at Toxteth Park, save for the three years 1632–35, which he spent as an undergraduate at Emmanuel College, Cambridge. The site of the house he was born in is now covered by the Otterspool Railway Station; his grave is in the grounds of the ancient chapel of Toxteth, a place of worship associated with the early Dissenters. Not far away is the Church of St. Michael's, and here in 1826, the Lancashire gardener-weaver-astronomer Moses Holden (1777–1864) erected the first memorial to Horrocks. In 1859 the Rev. A. B. Whatton published a translation of his "Venus in Sole Visa", together with a memoir of Horrocks; a memorial chapel and window were added in the same year to Hoole church, and when attention was again being directed to Horrocks's work by the transit of Venus of 1874, steps were taken to place a memorial in Westminster Abbey.

On November 12, 1874, NATURE recorded the permission given for the erection of this memorial, and a list of subscribers, headed by the names of Adams and Airy and including those of Christie, De la Rue, Lassell, Lockyer, Proctor, and "the Village of Hoole". The memorial in the Abbey, unveiled in 1879, consists of a scroll placed within the monument to John Conduitt, the nephew of Newton, at the west end of the nave. Owing to Horrocks's premature death, and the confusion of the times, some of Horrocks's manuscripts were lost. That of the "Venus in Sole Visa" was saved, and a copy passed to Huygens and then to Hevelius, who published it in 1662. Other manuscripts were published by John Wallis in 1673, and these showed that Horrocks had views on many subjects far in advance of his time. In Manchester Town Hall there is a fresco by Madox Brown recalling the observation of the transit of 1639, but in this the scene is Manchester and the central figure is Crabtree.

Psychology of Joan of Arc

IN a paper entitled "A Medico-psychological Revision of the Story of Jehanne La Pucelle" read before the Section of the History of Medicine of the Royal Society of Medicine on December 4, Dr. H. P. Bayon said that modern historians, by interpreting medieval religious conceptions according to the dictates of contemporary critical doctrines, have failed to examine the voices and visions of La Pucelle in their proper light and sequence. The first voices heard at the age of thirteen were, according to him, connected with endocrine activity tinged by intense religious fervour and could not be rightly diagnosed as morbid, even if they ranked as somewhat abnormal. A couple of years after, the simple monitions of the voices were followed by visions and commands, directing the Maid to perform valiant military deeds for a patriotic service; these must be classified as something additional, since their purpose was creative and constructive and furthered the accomplishment of a certain preconceived plan by providing confidence in her mission and obtaining authority for her message. Joan of Arc thus became instinctively the first protagonist of that form of national patriotism which was to play such a part in arranging States and dynasties in Europe during succeeding centuries.

Her courage and perseverance could be matched by other heroines in history; the boldness of her patriotic conceptions was unique, not only for her age and sex, but also because of her youth and lack of military education. In constructive leadership she far surpassed Christine de Pisan, who had full opportunities for obtaining the knowledge requisite in formulating the teachings of French nationalism. Even if her voices and visions were diagnosed as hallucinations, there was no reason to consider these as part of a system of morbid delusions. Not only their form and content but also her subsequent behaviour provided full evidence that she conceived, planned, and put into execution a programme of national survival which obtained historical significance. Such achievements could not be the outcome of the wild vapourings of insanity; they must be the work of creative genius.

Chemistry at St. Andrews

SIR JAMES IRVINE, principal and formerly professor of chemistry of the University of St. Andrews, reviewed the history of chemical teaching at the University in an address on December 6 before the University of St. Andrews Chemical Society. The story goes back, Sir James said, to 1808, when the University accepted a gift of £1,500 from Dr. John Gray, of Paddington, to institute and maintain a chair of chemistry at St. Andrews. This sum was totally inadequate to found the chair, and no appointment was actually made until 1840. While Sir David Brewster was principal of the University, the endowment was brought up to £2,700, and Dr. Arthur Connell was appointed the first professor of chemistry. Connell, who became an authority on mineral analysis, was succeeded in 1862 by Prof. Matthew Forster Heddle. Heddle devoted his attention chiefly to mineralogy; among his students were James Stuart, afterwards the first professor of engineering at Cambridge, Francis Robert Japp, who became professor of chemistry at Aberdeen, William J. Matheson, an American who founded an entrance scholarship and a bursary for chemistry at St. Andrews, and Thomas Purdie, who was to succeed Heddle in the professorship.

Purdie's occupancy of the chair marked a turning point in the history of chemistry and in the history of the University of St. Andrews. In his inaugural address, he stressed the "high educational value" of research; he introduced the study of organic chemistry, and he succeeded in establishing a research laboratory, the first of its kind in Scotland. An uncle of Purdie's left him a large sum of money, which he used to build a laboratory, and he had the satisfaction of seeing his research school well established. Purdie was succeeded in 1909 by Sir James Irvine himself, who continued in the chair until 1920, when he became principal of the University. The next occupant was Sir Robert Robinson, who was followed in 1922 by Prof. John Read. Summing up, Sir James pointed out that the St. Andrews chair of chemistry had had six occupants, five of whom, including the present holder, were fellows of the Royal Society; it had trained sixteen professors and one Government chemist. Altogether, this is a notable record for a chair which has been functioning for just a hundred years.

Health Conditions in Guatemala

IN a recent message to the National Legislative Assembly, General Jorge Ubico, the president of Guatemala, gives the following details concerning health conditions in that country during 1939. 324,031 treatments were given to 67,371 malaria patients, 85,407 persons were treated for intestinal parasites, 2,486 dysentery cases received 13,123 treatments, 4,073 onchocerciasis patients were treated, 64,640 treatments for venereal disease were administered and 250 women were given 7,725 examinations. There were mild epidemics of whooping cough, diphtheria, measles and typhoid fever. The country has seventeen departmental hospitals, which cared for 48,815 persons.

Recent Earthquakes

ON December 20, at about 2.30 a.m. local time, an earthquake shook a wide area in the north-eastern United States and south-eastern Canada. It is reported to have been felt by people for some forty-five seconds in parts of Massachusetts, Maine, Connecticut and Rhode Island, and for a shorter time and less severe in Long Island, New York and New Jersey. In Montreal thousands of residents were awakened by the rattling of loose objects such as crockery on shelves, but no damage or casualties are reported. Another shock affected the same area on the morning of December 24, but only minor damage was caused and no casualties are reported. It is anticipated that the United States Coast and Geodetic Survey and other seismologists in the United States and Canada will be examining both instrumental and macroseismic evidence of the shocks, and any report is awaited with interest.

Also on December 20 an earth tremor was reported to have been felt for several seconds in the lower valley of the Arno River near Florence in Italy. Two earthquake shocks rocked the Erzinjan district of Turkey in the early hours of December 25, according to a message from Ankara. No damage or casualties are reported. The great Turkish earthquake in the same district occurred at 1.57 a.m. local time on December 27, 1939 (NATURE, January 6, 1940).

Comet Cunningham

A SHORT notice about this comet was published in NATURE of November 2 (p. 587). More recent observations have enabled Mr. Cunningham to compute a better orbit, the elements of which are given below:

T	.. ..	1941 Jan 16.25204	
ω	.. ..	199° 35·5′	1940·0
Ω	.. ..	295 42·2	
i	.. ..	49 51·8	
q	.. ..	0·36822	

An ephemeris is given, commencing January 2. The comet is moving rapidly southwards, and after January 10 it will be too close to the sun to be observable. On January 6 it will be near ι Aquilæ and should be easily visible to the naked eye.

Announcements

M. HENRI BERGSON, the celebrated philosopher, has refused to be exempted from the clauses of the new statute relating to Jews in France. The exemption was offered him for "exceptional services rendered to literature, science and art". He will therefore have to resign his chair at the Collège de France.

PROF. ROBERT D. DEFRIES has been appointed director of the School of Hygiene and of the Connaught Laboratories, University of Toronto. During the past twenty-five years he has been prominent in the work of these two institutes, having early in 1915 become actively associated with the late Prof. J. G. Fitz-Gerald, whom he now succeeds.

IN Administrative Memorandum No. 255 the Board of Education refers to the considerable risk of fire due to breaking of bottles containing dangerous chemicals in the event of a school being bombed. Those responsible should take precautions to minimize the risk. Only the smallest quantities of those chemicals, in particular, sodium, potassium, phosphorus, ether and strong acids, should be kept in the building and they should be stored in metal containers.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Stationary Electric and Magnetic Fields in Beams of Light

ACCORDING to the electromagnetic theory of light (Maxwell, Hertz) the electric light vector and the magnetic light vector oscillate perpendicularly to the direction of propagation. The energy of the wave is given by Poynting's vector.

It is shown below, on the basis of experimental findings, that every wave of light possesses likewise a stationary field intensity E in its direction of propagation and also the stationary magnetic field of intensity H. That means there is a potential difference between two points on the ray of light. Accordingly, it should be possible to collect electricity from the ray under suitable conditions. A beam of light therefore constitutes a source of electricity; furthermore, light has magnetizing effects.

Experimental proof of this generalization was obtained from my investigations of the interaction between light and small particles of matter[1]. This permits of the measurement of forces of the order of 10^{-9} to 10^{-10} dynes. The sensitivity of measurements of forces is thus increased by my methods by a factor of 1,000–10,000.

When particles of matter are irradiated by sufficiently intense light of sufficiently small wave-length, regardless of the direction of the wave front normal, then positive or negative electric charges, or north or south magnetic poles, are induced on these particles. Particles of otherwise identical properties move in a homogeneous electric or in a homogeneous magnetic field in or against the direction of the electric field (electro-photophoresis), or in or against the direction of the magnetic field (magneto-photophoresis). These induced temporary electric or magnetic ions exist as long as the particles are irradiated by sufficiently intense light. Furthermore, it can be observed that some particles stay at rest and that their motion commences suddenly, or that moving particles appear to change their velocity and even reverse it. These are due to changes of charge. The movement of magnetic ions in a homogeneous magnetic field is a 'magnetic current'.

These phenomena are best observed when *two* fully symmetrical beams of light are directed against each other and when the fields act perpendicularly, are reversible and free from residual magnetism and electricity, and are also homogeneous. The intensity of this motion depends upon the frequency of the light wave. It increases with increasing frequency and is also dependent on the material. I have also found that, when using just *one* concentrated beam of light, without any field, small particles of matter of magnitude 10^{-4} to 10^{-5} cm. of the same kind as before moved in clean gases either away from the source of light (light-positive, longitudinal photophoresis) or towards the source of light (light-negative, longitudinal photophoresis). This force increases with the intensity of the light and likewise depends upon frequency and material.

There are particles which do not show longitudinal photophoresis at first, but only after a certain time, and some which gradually lose it. I have shown in another paper also that radiometer forces cannot account for these effects[2]. Longitudinal photophoresis has also been found in liquids with particles of the same material. These particles moved in opposite directions (Satiendranat Ray, Lucknow; W. Barkas, London).

Since light makes particles of matter unipolar with respect to homogeneous electric fields, and since, when no such fields act, it makes them move in or against the direction of its wave front normal, there must be an electric field E coincident with the direction of the wave front normal. This means that electromagnetic waves possess longitudinal stationary components of E, and therefore potential differences between different points along the beam. The magnitude of those fields can be calculated from actual measurements.

These facts have been confirmed by further experiments by myself and by some of my pupils. An electric field suitably arranged *parallel* to the wave front normal permits the acceleration or retardation or even reversal of positive or negative photophoresis. The superposed field alters the component of the electromotive force in the direction of the beam.

From similar experiments it can be concluded that stationary magnetic fields exist in the beam of light, since superposed magnetic fields accelerate or retard the magneto-photophoresis. Those stationary magnetic fields in the beam of light have a magnetizing effect on the material as above mentioned.

In conclusion, I find that light beams have electric stationary components in the direction of the wave front normal, and that consequently there must be stationary electric potential differences between different points along the beam. There must also be a stationary magnetic field in the beam of light with potential differences.

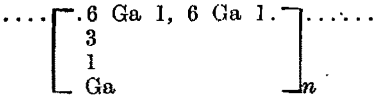
The ε-Galactan of Larch Wood

THE occurrence of this material, which is of considerable interest in connexion with the chemistry of wood formation, has been recognized for some time and it has been shown to contain *d*-galactose and *l*-arabinose residues[1]. In a recent article[2] descriptions are given of esters of this galactan and of its methyl ether, and the authors tentatively conclude that the substance hitherto designated ε-galactan is probably a mixture of a galactan and an araban. As the outcome of experiments carried out before the outbreak of war we had reached a similar conclusion, arrived at from a study of the hydrolysis products obtained from methylated ε-galactan. In view of the fact that Wise *et al.* have not dealt with the hydrolysis of the methyl derivative, we are now summarizing the main features of our results, which, although incomplete, had already given information concerning the structure of this galactan.

The arabinose residues, as shown by their rate of hydrolysis to free arabinose, possess the furanose structure which has been found also in all the naturally occurring arabans hitherto examined[3]. The galactan portion undergoes no appreciable change when subjected to the mild acid conditions which suffice to hydrolyse the araban. This is to be expected since (see below) all the galactose is present in the pyranose form. Furthermore, arabinose-free galactan thus obtained gives a fully methylated derivative $[\alpha]_D - 18°$ in methyl alcohol which is identical with the substance obtained by separation of the methylated galactan from the mixture of methylated galactan and methylated araban produced by methylation of the original ε-galactan. These observations provide strong evidence that the original ε-galactan was a mixture of polysaccharides and that the arabinose residues are not attached to galactose.

On hydrolysis the methylated galactan gave rise to the following products: (1) 2 : 3 : 4 : 6-tetramethyl galactopyranose (1 mol. proportion), (2) 2 : 4-dimethyl galactopyranose (1 mol. proportion), (3) trimethyl galactopyranose (1 mol. proportion). This consisted mainly (perhaps entirely) of 2 : 3 : 4-trimethyl galactopyranose, but with the evidence at present available it is just possible that another trimethyl galactose (2 : 4 : 6 ?) might also be present. (4) A methylated uronic acid is present in very small amount.

These results establish the general type of structure present in the galactan. The three galactose residues which comprise the repeating unit of the galactan molecule are respectively: (1) a terminal galactose residue attached only through C_1; (2) a residue attached to the others through C_1, C_3 and C_6; and (3) a residue attached through C_1 and C_6 (with the possibility, referred to above, that in some residues the junctions may be through C_1 and C_3, depending on whether the presence (in the products of hydrolysis) of 2 : 4 : 6-trimethyl galactose is or is not established). The problem is formally similar to that discussed in papers on the arabans[3]; and as a particular example of the general type to which the structure must conform the following may be cited, in which a chain of β-linked galactose residues has another residue attached laterally as a side chain (Ga = galactopyranose residue):



$$\ldots\left[\begin{array}{l}.6\ \mathrm{Ga}\ 1,\ 6\ \mathrm{Ga}\ 1.\\ \ 3\\ \ 1\\ \ \mathrm{Ga}\end{array}\right]_n\ldots$$

There are obvious variations of this, between which no decision can yet be made. It is not possible to give a definite estimate of the chain-length of the molecule, although it may be mentioned that from viscosity data a molecular weight of about 2,300 has been suggested[4], and the significance of the uronic acid residue present in small amount is not yet apparent. This type of structure is similar to that present in plant gums and reveals a striking general resemblance between this galactan and the araban of pectic materials, although the ring structures of the constituent sugars differ completely and there is no possibility that such an araban could arise by oxidation and decarboxylation of this galactan.

Sesame Cake and Antler Growth

ON July 8, 1939, an article by a special correspondent of *The Times* directed attention to the beneficial influence of sesame cake on the growth of antlers. In trials at the London Zoo the antlers of a reindeer, a wapiti and a red deer no less than ten years old considerably improved after they had received the cake. These results confirmed the wider experience of Mr. Franz Vogt, who had previously reported that antler growth among the red deer on his Czechoslovakian estate had increased fifty per cent after adding the cake to their ration[1].

The cause of the stimulation of antler growth is uncertain. The question was brought to our notice by Prof. Julian Huxley. After discussion with him a few experiments were planned to throw light on the problem.

There appeared to be two possible explanations. Either Mr. Vogt was correct in thinking that the sesame cake improved the nutritive balance of the diet of the animals, in particular making good a common deficiency of calcium, or the cake contained an androgenic or gonadotrophic substance effective on oral administration. The latter explanation seemed unlikely, in view of the fact that sesame oil has been widely used as a convenient solvent for administering sex hormones by subcutaneous injection; but it was thought to be worth while making a few experiments which should be decisive.

Accordingly, samples of sesame products were assayed for androgenic and gonadotrophic activity.

The androgenic assays were made with capons. The grain and mash ration was gradually replaced by crushed sesame cake and meal until after ten days they were each receiving 60 gm. of the products daily, supplemented by one feed a week of their normal diet. Measurements made at intervals during the two months period of treatment gave no evidence of comb-growth.

Sesame cake or seed was ground and mixed in equal parts with a normal rat diet, and each mixture fed to groups of immature female rats, for periods of 12 and 42 days. This resulted in an intake of each product of 2–3 gm. per day, and the growth of the animals was quite normal. Ovaries, adrenals, uteri and hypophyses were then dissected out and weighed, but in no case was there any indication of an increase in the weights of these organs. Histological studies of these and the thyroid glands showed no abnormalities.

These negative responses seem to dispose of the possibility of direct or indirect hormonal control of antler growth by any component of sesame products.

We are thrown back, therefore, on the alternative view, for which Vogt has already provided substantial evidence, that it is the high calcium content of the cake, and possibly other nutritive components, which facilitates rapid and increased development of the antlers.

Effect of Skin Coatings on Apples

IN recent years considerable attention has been given by Hitz and Hant[1], Kaess[2], Smock[3], Platenius[4] and others to the use of skin coatings for the preservation of fruits and vegetables.

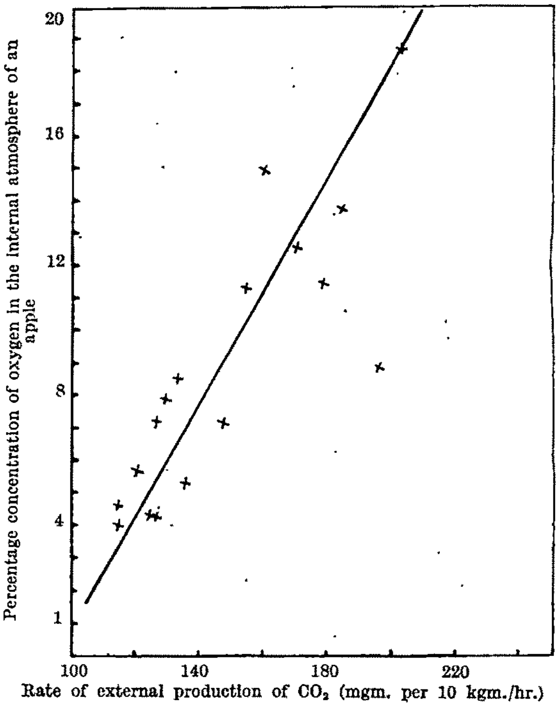
Experiments in this laboratory on Granny Smith apples have been carried out by investigators of the Division of Food Preservation of the Commonwealth Council for Scientific and Industrial Research in co-operation with the Department of Agriculture of New South Wales and the Botany School of the University of Sydney. The fruit was coated by dipping it in solutions of emulsions containing various proportions of oil, wax and shellac prepared so that the total solids were of the order of 5–10 per cent.

The relationship between treatments, internal oxygen and carbon dioxide concentrations, and external respiration has been investigated over a range of temperatures. The method used in analysing the internal gas composition was similar to that of Wardlaw, Leonard and Barnell[5] for papaws and bananas.

Smock and Platenius have shown that there is a marked lowering of oxygen consumption in fruits and vegetables treated with wax emulsions. Numerous workers have shown also that decreasing the external oxygen concentration (within certain limits) decreases the carbon dioxide output of pre-climacteric apples. Our results for pre-climacteric apples indicate that treatment with skin coatings reduces the internal oxygen concentration and thus the external output of carbon dioxide, but does not appear to increase the internal carbon dioxide concentration. The correlation between the internal oxygen concentration and the external output of carbon dioxide is shown in the accompanying figure.

As the storage period is prolonged, it seems that there is a gradual fall in the internal oxygen concentration of untreated fruits due to decreased permeability accompanying ripening changes, and eventually anaerobic respiration may occur. Though treatment with a skin coating may delay the onset of ripening changes, it will accelerate the fall in oxygen concentration when ripening does begin.

Prior to the onset of anaerobic respiration internal disorders may develop in fruit in which the internal oxygen concentration has been reduced to a low value by treatment with a skin coating. In this connexion it is interesting to record that lesions identical with 'brown-heart' developed in Granny Smith apples in which the internal oxygen concentrations were reduced to approximately three per cent by a skin coating but in which the internal carbon dioxide concentration was not significantly increased. Previously 'brown-heart' has generally been associated with fruit stored in atmospheres containing considerably more carbon dioxide than is present in air.



Alcoholic fermentation and internal disorders do not always develop after treatment, and in some cases skin coatings prolong the storage life. The conditions of picking maturity and storage under which a treatment may be beneficial for any particular variety of apple therefore require careful investigation. Other experiments with the Sturmer Pippin, Jonathan, Stayman Winesap, and Rome Beauty varieties indicate that different varieties respond very differently to the same treatments.

Detection of Clay Minerals in Soil Mortars by Photo-electric Cell

A RECENT communication by V. L. Bosazza[1] lends point to a description of the application of the photo-electric cell to the determination of the nature of the clay minerals present in soil mortars. After treatment with a solution of malachite green for a period of 10–15 min. to permit of base exchange, the liquid is filtered into a glass cell. The degree of decolorization of the filtrate is a measure of the amount of base exchange between clay minerals and stain, and this can be evaluated quantitatively by placing the filtrate between a light source and a photo-electric cell having a sensitive galvanometer in circuit. Clay fractions which are dominantly quartzose in type remove little of the stain, while those of the kaolinite or beidellite types produce an almost clear filtrate. Colour differences in the filtrates obtained from different clay fractions can then be measured by means of the galvanometer.

The importance of the mineral content of soil mortars has already been demonstrated[2], and the method outlined above offers a rapid means of detection of soil mortars rich in either kaolinite or beidellite clays. It is then only necessary to measure the relation between the volume of the soil mortar and its water content in order to distinguish between soil mortars with dominant kaolinite and those in which beidellite clays are the more abundant. In the former case the expansion is far less than in the latter on increase in moisture content.

It is very unusual to find any reference to the exact nature of the clay fraction present in gravels used for highway foundations when reference is made to the large American and other literature on this subject. Unless this fact is taken into account, serious foundation failures are likely to occur owing to the presence of dangerous clays having marked expansive properties, and it is clear from recent work in the Union of South Africa that the physical properties of the minerals forming the clay fraction are of dominant significance in determining the behaviour of such gravels under field conditions.

Reservation of Scientific Workers

THE classification of scientific workers in the Schedule of Reserved Occupations results in an extremely inefficient use of scientific talent for the national cause, and is giving rise to much bewilderment and exasperation.

The list includes a few highly special classes, and a few very broad ones, with a variety of ages of reservation. The difficulty is that many classes overlap, and that most scientific workers can with equal propriety be included in several of them. An early example arose from the separate classification of university teachers and research workers in universities. Most science lecturers do some research, and many of them devote nearly all or even all their time to research. Chemists, physicists, histologists (not human), exist side by side with the class which can cover them all, namely, that of "research worker in a recognised institution". In practice, this last class includes those whose specialities are not separately listed, and those who fall midway between other listed categories. A physical chemist, being neither quite a chemist nor quite a physicist, would register in the general class, with the result that he is now reserved at thirty, instead of at twenty-one, as he would have been had he called himself a physicist.

The situation, which is certainly most worthy of contemplation, is that of a scientific worker being called up while his own laboratory assistant is left. This has already happened, and must soon be happening on a large scale, for the laboratory assistant is reserved at twenty-five in his trade capacity and at twenty-one for general service, which has meant, in practice, that he is reserved at the lower age. Yet it usually takes the man of science as many weeks to train his assistant as he himself took years to be trained.

A most remarkable complete omission from the list is that of mathematician; if he applies his mathematics to physics he may be reserved as a physicist, but if his mathematics are sufficiently 'pure' to be applicable to all sciences, then he is not reserved at all. A biologist, who has specialized in genetics, may be of the greatest use to agricultural research, but he will be called up under thirty, because there are too few geneticists to make a separate category.

These anomalies have given rise to the curious practice of changing the description of the occupation on the Ministry of Labour Index, as ages of reservation alter. A more rational procedure, and one which would give less work to the departments concerned, would be to make individual reservations on the basis of information filed at the Central Register. Since this information was recorded before the issue of the Schedule it would be unbiased by any consideration of reservation ages and, moreover, includes proper particulars of capacities to do work outside the present occupation.

Early Post-Glacial Conditions in England

DR. L. HAWKES'S[1] interesting letter raises wide issues, if (as we believe should be done) the more precise term 'early Post-Glacial' be substituted for 'Pleistocene'. That a tundra condition in Britain succeeded the disappearance of the Pleistocene ice-sheets now seems more than probable. Evidence for this is widespread. In the great sand-pit at Greenside, north Durham, one of us (W.A.) in 1936 noticed several 'sand-dykes' with funnel-shaped tops, which we agreed were due to frost cracking. Since then many other instances have been noted in north-east England, always in surface deposits, and usually, though not invariably, in gravels; and solufluxion phenomena are known on the Yorkshire coast, while other tundra phenomena abound in the north Lincolnshire gravels.

These data confirm Kilroe's[2] admirable description and figure (made so long ago as 1908) of frost-cracks in some north Irish gravels, and recorded by him as proof of tundra conditions. Each and all are definitely Post-Glacial. They are therefore presumably contemporaneous with Nehring's tundra period of the north German Plain. May it not be that Reid's[3] "thoroughly Arctic fauna and flora", so well known in the south of England, as seen in the Coombe Rock and other deposits, are of similar date?

RESEARCH ITEMS

Bronze Age Cemetery near Glasgow

IN May 1936, the discovery by a workman of "a strange old pot" at Springhill Farm, Baillieston, near Glasgow, led to the identification of a cemetery site on which excavations were carried out by J. Harrison Maxwell, so far as agricultural operations allowed, in the months following until the next sowing for crops (*Trans. Glasgow Archæol. Soc.*, N.S. 9, 4; 1940). The cemetery contained three cremation burials. The first burial found was indicated by two food vessels, of which one, rather squat, was remarkably beautiful. Here no human remains were definitely detected, but carbonized wood nearby may indicate either a wooden vessel or a cremation burial. The second burial was a cist with two lots of cremated bones. Although no grave goods or pottery were found, it had all the characteristics of a bronze age burial. Two small heaps of ashes were found on top of the north cover stone; nineteen white quartz pebbles were associated with the bones. A remarkable feature of the north cover stone was a cut-out, somewhat oblong in shape, measuring 6⅝ inches by 3½ inches and about half an inch in depth. A shallow groove runs through the middle of the cut-out and across the stone. The cist was of unusual form, being tongue-shaped, measuring 4 ft. in length and 21 in. in greatest breadth at the south end. A blue glass bead was found at a depth of 2 ft. about 20 ft. from the Food Vessel site. Six inhumed burials were found, but in the absence of pottery, etc., cannot be dated. Two square pits containing charcoal and iron slag prove the existence of a bloomery here in the Early Iron Age or later.

Anuran Parasites

SEVENTEEN years ago, Maynard M. Metcalf gave an account of the opalinid ciliate infusorians which, with few exceptions, are found in the anuran amphibians, in which they are widely and generally distributed. The author himself has continued the work in the interval and other workers have also added both to the number of known species, the life-histories and the cytology of the family. This work is now reviewed in considerable detail by the same author (*Proc. U.S. Nat. Mus.*, **87**; 1940). The two publicalications constitute a monograph of the Opalinidæ. In the present paper thirty new species are described and illustrated, as are also the species recorded by other workers in the interval. Perhaps the most interesting section for the general reader is that dealing with the geographical distribution of the parasites and their hosts. It is illustrated by numerous maps, and gives the author an opportunity of speculating on the phylogeny of both the Anura and the Opalinids.

Corpus Luteum in Reptiles

SINCE the endocrine functions of the corpus luteum are so intimately bound up with phenomena essentially associated with mammalian reproduction, it is interesting to find that a similar organ is developed in reptiles. A good account of it in a gecko, *Hoplodactylus maculatus*, has been given by Mary M. Boyd (*Quart. J. Micro. Sci.*, **82**; 1940), who also provides a description of the ovary and various stages of oogenesis. As in other craniates laying megalecithal eggs, a prolonged diplotene stage is passed through. The egg is provided with a striated membrane composed of material similar to that of the zona pellucida. The epithelial wall of the follicle, originally many-layered and exhibiting three different types of cells, is reduced to a single layer. The corpus luteum itself is very similar to that in the marsupials and is composed of luteal cells and fibroblast cells from the theca externa, but the cells of the theca interna do not take part in its formation. While a lipoid secretion is present in the luteal cells, there is as yet no experimental evidence as to its functional significance.

Placentation of Hyrax

A FULL account of the placentation of *Procavia capensis* is given by G. B. Wislocki and O. P. van der Westhuysen (Cont. to Embryology, Publ. Carnegie Instit., **171**; 1940). It is found that a transient yolk-sac and a permanent allantoic vesicle are represented, the latter developing into a large four-chambered sac. The trophoblast proliferates over the entire surface of the blastocyst. A trophoblastic network is formed into which chorionic mesoderm gradually penetrates. The placenta is of the hemochorial type. The memoir is well illustrated, and the authors' conclusions may be quoted. "The placenta and fetal membranes of Procavia, the elephant and the manatee exhibit very close structural affinities. Furthermore, the peculiar configuration of the allantoic sac and its vessels is practically identical in Procavia and in lemurs; otherwise placentation in these two groups is quite dissimilar. The mode of development of the placental labyrinth in Procavia resembles very closely that occurring in Tarsius. The marked similarities between the placentæ of Procavia, Elephas and Trichechus are interpreted as indicating phylogenic affinities, whereas the similarities between Procavia and the lemurs and the tarsoids are regarded as representing independent, parallel lines of development."

Central American Plants

DURING 1938–40 two botanical expeditions to Guatemala were led by P. C. Standley and J. A. Steyermark of the Field Museum, Chicago. All but one of the twenty-two provinces of the country were visited and very extensive collections were made. A preliminary report has been published (Field Mus. Nat. Hist., Bot. Series, 22, No. 4; Sept. 1940) containing descriptions of some of the many new species discovered together with notes on plants new to the country and otherwise notable species. Forty-six new species and four new genera are described. An outstanding discovery was a plant which the authors have named *Rojasianthe superba*. This they describe as "one of the most elegant and beautiful plants we have ever seen" and "one of the handsomest and showiest of the Compositæ ever collected". It has large heads with paper white or lilac tinged ray florets and black disk florets; in habit and appearance it suggests an affinity with Dahlia, but it possesses highly distinctive generic characters. It was discovered in ravines in the mountains of western Guatemala ranging from 7,000ft. to 12,000 ft., and the authors believe that it might flourish in southern England. It is remarkable that a plant of such exceptional beauty and horticultural merit should have escaped detection for so long. Another new genus is Orthion (Violaceæ) from northern Guatemala and British Honduras. Two arborescent species are described, one a tall tree attaining 18 metres with a trunk 45 cm. thick.

The Composition of Human Hair

IT is known that eukeratins, for example, wool and hair, are distinguished from pseudokeratins in that their basic amino-acids (histidine, lysine and arginine) are found in a relatively constant molecular ratio of 1 : 4 : 12. The proportions of non-basic amino-acids show wide variations, particularly with respect to cystine, a high content of which is characteristic of keratins. Previous workers have reported no constant relation between cystine content and colour, age or sex, although there was an apparent tendency for the values to be larger in adult hair. R. C. Clay, K. Cook and J. I. Routh (*J. Amer. Chem. Soc.*, 62, 2709 ; 1940) have made experiments on the cystine, cysteine, nitrogen and sulphur content of 120 samples of human hair. No consistent relation between age and composition was found. There was more cystine and cysteine in male than in female hair. Dark hair contained more cystine than light hair. No significant variations in the nitrogen and sulphur content were observed.

Oxygen Exchange between Water and Anions

THE use of heavy oxygen ^{18}O as a means of investigating the mechanism of certain reactions has been recognized and many investigations in this field have been made, and some general conclusions have been drawn. The rate of reaction is often determined by the *p*H of the solution. The exchange of oxygen between water and the chromate, hydrogen sulphate, sulphite, metabisulphite, thiosulphate and permanganate ions, under conditions of varying temperature and *p*H, has been investigated by G. A. Mills (*J. Amer. Chem. Soc.*, 62, 2833 ; 1940). Exchange with sulphates in acid solution agrees with the reversible formation of anhydride $H_2SO_4 = H_2O + SO_3$. The exchange with chromates proceeds faster than can be accounted for by the reaction $Cr_3O_7'' + H_2O = 2\,HCrO_4'$ and the reaction $CrO_3 + H_3O = H_2CrO_4 = H^{\cdot} + HCrO_4'$ is suggested. No exchange was observed with potassium sulphite. No evidence of direct interchange of oxygen atoms was found. For some anions addition and subsequent removal of H_2O or OH' to the anion is apparently the mechanism, whilst with the bicarbonate ion previous work has shown that the mechanism is hydrolysis to form undissociated acid followed by reversible anhydride formation. The last mechanism is shown to account for the exchange reactions with inorganic oxy-anions.

Heat of Hydration of the Proton

THE heat of hydration of the proton : H^+ (gas) + Aq. = H^+_{aq} may, as is known, be calculated by the Born-Haber cycle applied to a halogen hydracid H*x*. The calculation involves a knowledge of various magnitudes, some of which have recently undergone revision, and also some assumptions. E. C. Baughan (*J. Chem. Soc.*, 1403 ; 1940) has recalculated the value for all four halogen hydracids, arriving at the average value of 282·5 k.cal. (± 3 k.cal.). The heat of hydration of the proton is required in the application of cycles of the Born-Haber type to acids and bases, and this new value appears to be preferable to the one previously calculated from the data for HCl only. It should be remembered, however, that several assumptions have been made in the calculation.

The Surface of Mars

THE close approach of Mars to the earth a year ago provided a favourable opportunity for close observation of the planet's disk from southern latitudes. Dr. E. C. Slipher of the Lowell Observatory, who obtained some 8,000 photographs from South Africa during the summer of 1939, describes his work in the *Telescope* of September–October 1940. The article is illustrated with nearly forty half-tone reproductions of selected plates ; from these excellent copies some idea can be obtained of the fine detail reached by the original photographs. The irregular changes noted during the opposition were striking and are described in some detail ; the seasonal changes followed their expected course and are dealt with briefly. Dr. Slipher claims that his photographs record so many of the 'canals' and 'oases' in the positions and of the forms shown on Lowell's maps of the planet that the reality of these markings must now be regarded as beyond doubt. A recent suggestion that the canals are divisions between areas of unequal shading is discounted ; no example has been discovered where the surface brightness on the two sides of a canal shows any visible difference. The colour-filter photographs suggest that the hazy north polar hood, which showed very rapid day-to-day variations of form during the 1939 opposition, is atmospheric in origin ; it precedes and accompanies the deposition of the more brilliant white polar cap, and may consist of very fine ice spicules.

Variable Extent of the Atmosphere of Zeta Aurigæ

A. BEER (*Mon. Not. Roy. Astro. Soc.*, **100**, 8–9 ; June 1940) has discussed material relating to the 1937 eclipse of this star, though the observations were made difficult by the low altitude of the star and by cloudy periods. The chief point in the paper is concerned with the remarkable behaviour of the *K* line of Ca II, and as this is produced in the extensive atmosphere of the *K*5 giant, significant changes in the structure of the atmosphere of this star are indicated. The new spectroscopic material covers about a month before the beginning of the 1937 eclipse (April 21·85) and the spectrophotometric investigation of the material was performed with the recording photomicrometer of the Solar Physics Observatory, Cambridge. Christie and Wilson (*Astrophys. J.*, **81** ; 1935) derived a theoretical expression for *N*, the number of atoms in the line of sight, based on Milne's theory of chromospheric equilibrium, and the failure of the 1934 observations to support the theory led them to remark : "Accordingly we conclude that the observations of the Ca ii envelope surrounding ζ Aurigæ are in disagreement with the predictions of Milne's theory." Fundamental changes in the atmosphere of the star during the 1937 eclipse do not allow this conclusion to be maintained, and, as Beer points out, there is now a much improved agreement with Milne's theory.

It is suggested, therefore, that the Egyptian of the time of Menes was starting his year with an observation of the reappearance of Sothis. The threefold division of the year was borrowed from prehistoric cus[illegible] with some modifications. The three seasons, [illegible] spring and harvest, each consisted of 120 [illegible] The 'moons' were continued as 'months' for [illegible] purpose of 30 days exactly, or three ten-day [illegible] and the year consisting of twelve months [illegible] days "over and above the year", subject [illegible] of one day or more owing to inaccurate [illegible] and the occurrence of an extra day each fourth year. This endured during the first two dynasties, yet it is known that throughout the later historical period the year differed from the star and the Nile. When was this "wandering" year first used ? Between 1317 B.C., when the New Year coincided with the appearance of the star, and 2773 B.C., there are several items of evidence that the civil calendar was consistently 'wandering' and at variance with the true seasons by about one day for each four years which had elapsed since 2773 B.C. The conclusion is inescapable that in that year the calendar had been in agreement with that star, and that in that year the observations on which that relation had depended were discontinued. The date is astronomically fixed as the start of the wandering calendar of succeeding centuries.

It is suggested that the change may have taken place in connexion with the period of prosperity which followed on the accession of Djoser, founder of the Third Dynasty, in 2778 B.C. The host of census takers, tax collectors and royal scribes who were engaged in managing the land under a powerful centralized government no doubt found a year whose beginning depended upon the observation of a star highly inconvenient, and preferred to adopt a year with a definite period of 365 days. Owing to the discrepancy between this year and the heliacal rising of Sothis amounting to one day in each successive period of four years, by a century or so later it became necessary to observe two New Year days, "the Opener of the Year" or "the Coming Forth of Osiris" and "The First of the Year", the latter in all likelihood being the New Year inserted into the calendar when it became definitely and obviously separated from Nature. When the calendar became less and less dependable in foretelling the true season, it was probably the time at which the priests invented the coronation oath which called for the new king to swear "never to intercalate a month or a day, nor to vary a festival, but to preserve the 365 days as they were ordained of old".

On the view here put forward the ancient Egyptian calendar was not an invention on any one day at dawn, when a series of phenomena happened to coincide, but it was a gradually developed method of predicting approximately the almost unpredictable rise of the Nile. For a few centuries before 2773 B.C. it depended upon observation of the reappearance of Sothis, and the resulting self-adjusting year was as true a measure of solar time as was the later Julian year. As man became more cultivated he felt the need of some measure of time-reckoning more definite than Nature itself. In 2773 B.C. he dropped the New Year observations and took up the 365-day year, which actually brought his seasons back into their original places only once again during his whole history.

THE FUEL RESEARCH BOARD

THE report of the Fuel Research Board for the year ending March 31, 1939, has recently appeared*, As this date was passed more than one and a half years ago the contents have lost their freshness. They reveal the measure of activity of national research on fuel problems before the outbreak of war and allow the reader to judge of the use made of the results.

The report opens with the work of the coal survey—one of the most important branches of the Board's activity. To realise this it is only necessary to recall the limited and superficial character of the scientific data about British coals during the War of 1914–18. The information accumulated in the meantime has already been turned to good use. It is also noticeable that the survey officers have passed the mere compilation of analytical data and have been able to reach valuable conclusions about the properties and applications of coal and the geology of the coalfields.

The growing importance of coal preparation is shown by the length of the relevant section, which reaches forty pages. Coal users are no longer content with any fuel, and even the householder is unwilling to receive and break under his own roof large lumps of fuel. Modern housing is not designed to store large stocks of dirty material which necessitates manual preparation before use. Effort is being made to prevent dust by coating lump coal with oils and hygroscopic salt solutions - problems which give rise to interesting physical problems. Although the distribution of fuel in fluid form has obvious advantages, war-time conditions show that there is merit in the possession of household stocks of solid fuel which a dispersed population can enjoy.

Oil synthesis from coal by different routes occupies the largest share of the report. Coal and coal tars—particularly the latter—form a source of liquid fuel. Hydrogenation of tars and oils was applied first to low-temperature tars and continued with gasworks tars, then coke-oven tars. As the work has proceeded the discovery of more active catalysts has enlarged the scope of the process.

The production of lubricants from coal has proved more difficult than the production of fuels, at any rate by hydrogenation. More promise is shown by synthesis from mixtures of carbon monoxide and hydrogen—the so-called Fischer-Tropsch process. By polymerization, certain fractions have been converted to products similar to natural lubricating oils suitable for internal combustion engines. Although these were not equal to the Air Ministry's standard, the hope is expressed that this will be reached.

---

* Department of Scientific and Industrial Research. Report of the Fuel Research Board for the Year ended 31st March 1939, with Report of the Director of Fuel Research. Pp. iv+206. (London: H.M. Stationery Office, 1940) 3s. 6d. net.

The use of gas producers for propelling road-vehicles has been studied at the Fuel Research Station since 1923 and in recent years more intensely. The work reported has been concerned mainly with the choice of suitable fuels and done largely in close association with the officers of the Coal Survey. The number of vehicles propelled by producer gas and seen on the roads is relatively small—possibly because the need for petrol substitutes has not been too pressing. There has, however, been no lack of scientific and industrial effort.

The section on domestic heating is largely concerned with the measurement of smoke emission and the means for its abatement. It was found that design of fire-places conducive to securing admixtures of products of combustion with air and to conserving their high temperature would make a considerable reduction in smoke. Unfortunately, present circumstances do not make the advantages of smoke reduction so evident as they will be when peace returns.

H. J. HODSMAN.

FORTHCOMING EVENTS

Wednesday, January 8

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1.) at 2.30 p.m. Prof. S. Zuckerman: "The Problem of Blast Injuries."

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PRINCIPAL OF LISBURN TECHNICAL SCHOOL AND ORGANIZER OF TECHNICAL EDUCATION—The Secretary, Lisburn and Belfast (Rural) Regional Education Committee, Castle Chambers, Lisburn, Co. Antrim (January 15).

LECTURER IN MECHANICAL ENGINEERING—The Principal, Walsall Technical College, Bradford Place, Walsall (January 18).

ASSISTANT EXECUTIVE ENGINEERS in the Punjab Service of Engineers, Class I—The High Commissioner for India, General Department, India House, Aldwych, London, W.C.2 (quoting Appointment 1/11/A) (January 24).

PROFESSOR OF ANATOMY—The Secretary and Registrar, University, Bristol (January 30).

TEACHER OF ELECTRICAL ENGINEERING in the Smethwick Municipal College—The Chief Education Officer, 215 High Street, Smethwick.

SENIOR LECTURER IN MECHANICAL ENGINEERING—The Clerk to the Governors, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17.

AND OCCURRENCE IN GIPPSLAND, VICTORIA

E, in a desire to clarify the ard to the occurrence of oil in ed out a critical examination of e on the subject and has also paid to the Lakes Entrance region in a geologist, a palæontologist and a ngineer. The report of his findings issued this year shows that, in so far as the litera- oncerned, this is in many ways incomplete and, over, embodies a wealth of conflicting opinions. or example, the Oil Advisory Committee's report of February 1937 reflects a cautious but optimistic view of oil possibilities in the Lakes Entrance area, while another report issued by the same authority and only a year later takes a definitely pessimistic outlook of such possibilities. A third report issued by the Committee at the end of 1938 was as constructive as the preceding one had been destructive.

Mr. E. A. Kodyen's report, written in 1939, considered the possibility of repressuring the Lakes Entrance field, but met with little support and definite opposition from Dr. A. Wade. Mr. F. Chapman advanced the view that there is a considerable thickness of "granite wash" below the glauconite or oil horizon, but this was not accepted by the Mines Department, which contends that the glauconite rests on or near bedrock. In spite of the importance of this point, reluctance was shown to permit the Government drilling plant to be used to decide the question. In 1937 Dr. Arthur Tieje visited the field and afterwards urged that a more complete and detailed study of underground structure should be made; but the investigation is still far from complete.

Sir Edmund Teale in his report maintains that incontrovertible data are still insufficient to permit accurate estimates to be made of proved resources. Moreover, investigations are not far enough advanced for any recommendations to be made as to the best method for recovery of the oil and the percentage which should be recovered. Nevertheless, results of carefully recorded tests carried out by the Austral Oil Company indicate that the area, if exploited, might be comparable with other low-pressure production fields in different parts of the world. Admittedly the oil is not petroliferous, but it yields three useful products, all of which have at present to be imported. These are bitumen, heavy oil and lubricating oil. In view of the usefulness of these products *per se*, it would not be necessary to consider the installation of cracking plants for the production of petrol. A disadvantage of the field is that it is definitely a low-pressure area where ordinary pumping methods are of little use. Some form of pressuring would be necessary and before embarking on any such scheme, expert advice would have to be procured.

During his inspection of the field, Sir Edmund visited Holland's Landing, near the western shore of Lake Victoria, where there is a modern plant in operation capable of attempting to penetrate the Tertiary deposits, which there attain a thickness of some 3,600 ft. In addition, sites were visited where scout drilling was in operation and also where boreholes had been completed and cores preserved for inspection. For the most part, however, there was evidence of much haphazard and unprofitable drilling carried out by private enterprise. Reliable records had not been kept until recently, when the Austral Oil Company undertook to make a series of regular tests from selected boreholes over a considerable period of time.

Sir Edmund's general impressions of his visit are summarized at the end of his report. Evidence of proved and potential oil in the Lakes Entrance area, in his opinion, warrants installation of approved methods to attempt recovery on a commercial scale. To this end the best technical advice procurable should be obtained. More geological information is required regarding the glauconite zone, the nature and thickness of underlying formations and the floor upon which they rest. Tertiary formations outside the Lakes Entrance area require special and more adequate exploration than is at present the case. Geophysical methods would facilitate this work.

Finally, in view of the present demand for oil of all kinds, Sir Edmund maintains that the undertaking should enlist the support of the Government and of private enterprise. Moreover, there is an urgency in the matter which calls for the immediate speeding-up of activities in this direction.

ORIGIN OF THE EGYPTIAN CALENDAR

THE calendar of the ancient Egyptians was one of the earliest experiments in calendar making, and it was one of the most enduring. It was still in use at the beginning of the Christian uch as it had been in the Pyramid age thre years before, having had an uninte ence throughout more than half of ma e. Many theories, all differing fu put forward as to its o recently by H. F Ancient Egypti sophical Soc., 83, No. 3; 1940), introducing a further suggestion as to the natural phenomena which first marked the changing seasons for the ancient Egyptians and came to be the foundation of their calendrical system.

The approach to the problem has usually started with a statement by Censorinus in A.D. 238 that the Egyptian New Year Day in A.D. 139 fell on July 21 when the bright star Sothis (Sirius), after having been invisible for a season, made its annual reappearance the eastern sky just before sunrise. Since the

Egyptian civil year was one of 365 days and the Sothic year was one of 365¼ days, this coincidence could have happened only at intervals of about 4 × 365 years or in 1317, 2773 and 4231 B.C. At the two earlier of these dates (assuming that 2773 B.C. fell in the Fourth Dynasty) the calendar was already in use; and hence Edward Meyer, in 1904, concluded that the calendar must have been introduced in 4231 B.C., since its introduction was possible only on the occasion of a coincidence of the opening of the Sothic and the calendar years. This dating, however, relegated the origin of the calendar to distant prehistoric days, long before King Menes, the first historical king who united the two lands of Egypt, and dated by Meyer himself at 3200 B.C.; consequently it involved the uninterrupted use of the calendar for a thousand years before the use of writing began.

The difficulties in the way of accepting such a conclusion led to numerous modifications of Meyer's theory by Breasted and others; but in recent years the tendency has been toward the more reasonable hypothesis that the calendar was the product of some later period. One of the most ingenious schemes for avoiding the difficulty is that of Prof. Jotham Johnson, who argues that the Egyptians had a lunar calendar until June 18, 3251 B.C., when the heliacal rising of Sothis coincided with a new moon. From that day the calendar was fixed to Sothis, but gradually became so far divorced from the terrestrial seasons that by June 18, 2773 B.C., a whole four-month season's correction was necessary and it was abandoned for the wandering year of the historic period. Another suggestion is that of Alexander Scharff, put forward in 1927, which attributes the invention of the calendar to 2773 B.C., but assumes that before then time was reckoned by an entirely different system, based, it would appear, on a year of 320 days. O. Neugebauer, however, had suggested that observation of the Nile flood over prolonged periods would give by averaging a year of 365 days without the observation of any heavenly body whatsoever, and this, Scharff holds, supplies evidence of the nature of the calendar in use before 2773 B.C. and possibly so late as 2000 B.C.

In this connexion it is pointed out that, certain modern studies on the Egyptian calendar notwithstanding, the whole history of a year with intercalations is a history of an innovation obnoxiously foreign to the native Egyptian; and there is no hint in the whole four centuries and a half covered by the classical literature that the Egyptians had any memory of ever having used a fixed year or of ever having recognized its desirability.

The calendar of the historic period gives clear evidence that it originated in the climate of the land. In this rainless climate all living things in the Nile valley have been dependent on the Nile flood. The river is at its lowest at the First Cataract about the end of May and at the head of the Delta some two weeks or more later. Soon after the level begins to rise, reaching its height at the First Cataract about September 1 and a month later at the Delta head, where by the middle or end of October the highest flood lands begin to emerge and the waters fall until they reach their lowest again in the following June.

From the palæolithic period onwards the occupations of the inhabitants, whether hunting, fowling and fishing, and pasturage when they acquired domesticated animals, or cultivating the seeds they had learned to save from the last low Nile—all these occupations were profoundly affected by the fluctuations of the Nile. In the season known later as *Akhet*, 'the [illegible] settlements on the [illegible] waters fell, *Proyet*, '[illegible] they followed the retre[illegible] plain; and in *Shōmu*, [illegible] meaning 'the harvest ti[illegible] and the permanent swamp[illegible] flood. Thus the ancient E[illegible] three seasons, and when he ad[illegible] he chose a form of *ronpy*, 'to b[illegible] as of plants, considering the year a[illegible] first signs of the rising water which [illegible] the verdure once more.

By the time stone age man felt the ne[illegible] other means of predicting the future sta[illegible] river, probably in connexion with the opera[illegible] agriculture, he must already have become accust[illegible] to counting the phases of the moon—with the ris[illegible] Nile four moons to the time of sowing, then four moons for the grain to ripen, and a third four moons before the flood would appear again. Notwithstanding the error in a lunar year of 354 days, and irregularities in the flood itself, the moon would serve as a practical rule of thumb. Traces of the lunar reckoning survived under a more practical calendar in the subdivision of the year into twelve parts, each called by the name of the moon, *abou*, as in our months. About 1850 B.C. lunar months of alternatively 28 and 30 days served for priestly temple service. Traces appear in religious calendars down to Roman times and the king was crowned on the day of the full moon. In 1100 B.C. astronomical tables still had a technical term for the mid-month derived from the time when a month was a moon and the mid-month was full moon time.

Lunar reckoning, however, was always of secondary importance for the Egyptians; and while other lunar calendars count each day from sunset, the Egyptians alone of all ancient peoples commenced their day at dawn and the same ideogram stood in their system of writing for "sun" and "day". Nevertheless the Egyptians never adopted solar seasons. Their seasons were always those of the Nile. Only for a brief period in the fourteenth century B.C. did Egyptian beliefs give full credit to the sun for its controlling influence on terrestrial life. It was only in classical times that the solstice was an omen of the coming inundation (*cf.* Herodotus and Pliny).

The rise of the Nile and lunar reckoning proving unsatisfactory as a means of time-reckoning for a people becoming more and more cultivated, and, the sun seeming to have no connexion with the question, the Egyptian, like other primitive peoples, turned to the sky for a sign that his new year was approaching. For this purpose he chose the heliacal rising of Sothis, which about 7000 B.C. was visible at the head of the Nile delta round about May 21 and in 3500 B.C. on June 17, and by 2800 B.C. on June 23. The later it came the more certain it was to be regarded as a harbinger of the flood. So early as the dawn of the historic period, that is, at the time of Menes, the Egyptian was already regarding Sothis as the harbinger of the all-important inundation. This is shown by a primitive ins[illegible]ion on an ivory tablet from a royal tomb at A[illegible]hich Sothis is called "Bringer of the New [illegible] the Inundation" and in a Pyram[illegible] te[illegible]f all green growing things [illegible] Thus the association wa[illegible] [illegible]he official observation [illegible]is to be noted, took [illegible] by Menes.

A WORLD PLANNING COMMISSION

THE twenty-five anonymous authors of the Penguin Special "Science in War" (see NATURE, July 27, p. 112) succeeded not only in presenting a review of a few of the many services rendered by scientific men in the present conflict, but also in leaving the impression of vast potential forces insufficiently co-ordinated or inadequately marshalled. Certainly many men of science in Great Britain feel that more direct use might be made of their special knowledge. It may be, as Dr. C. H. Desch has said, that "advisory committees of independent scientific men are appointed by many Government departments, but they rarely have the power to discuss policy, and still less often to make decisions, so that their work is liable to fail of its effect or to be subject to an unnecessary time-lag". On the other hand, there has been a growing realization that part of the blame rests with scientific men themselves, for many have shown lack of appreciation of, even a lack of interest in, the social consequences of their own work, so that it is left to the administrator to formulate plans and make practical applications of scientific discoveries or to set right dislocations of a slowly evolving social structure which a too rapid succession of discoveries inevitably causes.

During the meetings of the Eighth American Scientific Congress held in Washington, D.C., during May 10–18 last, several papers on the conservation of natural resources and allied topics were discussed, and the following resolution was passed :

> "WHEREAS : Needless waste and destruction of necessary natural resources everywhere threatens or will threaten, sooner or later, the welfare and security of peoples ;
>
> Throughout human history the exhaustion of these resources and the need for a new supply have been among the greatest causes of war ;
>
> The welfare of every nation requires natural resources which it lacks, and fair access to such resources from other nations is an indispensable condition of national welfare and permanent peace ;
>
> Conservation of natural resources and fair access to needed raw materials are steps toward the common good to which all nations must in principle agree ;
>
> International cooperation to inventory, conserve and wisely utilize natural resources to the mutual advantage of all nations might well remove one of the most dangerous obstacles to all nations to a just and permanent world peace ; and
>
> An Inter-American Conservation Commission representing all the American nations would be of great and lasting value to the Americas, and through them, to all the nations of the world by advancing the knowledge of the natural resources of the earth, by promoting mutual access to necessary natural resources, and by bringing nearer the permanent removal of one of the greatest causes of war,
>
> The Eighth American Scientific Congress
>
> RESOLVES : To recommend to the Governments of the American Republics the appointment of an Inter-American Conservation Commission cooperating with the Pan American Union and representing all the Americas.
>
> That this Commission be charged with the duty of preparing an inventory of world natural resources, and of formulating a general policy and specific program of action to promote the mutual conservation and prudent utilization of natural resources for the welfare of all nations, in the interest of permanent peace."

This resolution is of fundamental interest for several reasons, but particularly because it recognizes the obligation of a single Commission to bridge the gulf between its own findings and their practical application.

Actually this ambitious project is but an extension of the procedure which has been tried out in the United States. There, after a small and tentative beginning, the National Resources Board was created as part of the Roosevelt 'New Deal' legislation by executive order on June 30, 1934, and charged with the tasks of preparing a detailed inventory and a general plan for the use of the nation's resources. In the following year a Bill was presented in the Senate for the establishment of a permanent National Planning Board. Thus the great work of reconstruction and conservation has been based on the survey initiated by Delano (uncle of the President), Wesley Mitchell and Charles Merriam, with Charles Elliott III as their organizing secretary.

The scope of the prospective world-wide inquiry may be judged from the elaborate and voluminous reports of the National Resources Board. These have been epitomized for the general reader in an unofficial volume by twenty-two authors entitled "Our Natural Resources and their Conservation" (New York: Wiley, 1936). Its ten parts deal respectively with the history of the conservation movement, the conservation of the land and its soil, forests and timber, water supply and power, minerals, wild life, recreational resources, man, the relation of conservation to industry, local, State and national planning.

With the advantages of a common tongue, a unified government control and a uniformly high standard of education, the survey of the resources of the largest free-trade area in the world was in the main a collecting of material already available. The extension of such a survey to all the American republics, and still more to the world as a whole, obviously bristles with difficulties. In the dictator countries, both the knowledge and the planning based thereon are the prerogatives of the *Führer* or *Duce*; in the communist organization, it is the State which nominally formulates and controls its 'five year plans', based on information unavailable outside official circles immediately concerned. Among the democracies, so long as there is free competition and the stimulus of reward to individual effort, much of the essential information is jealously guarded by those individuals or corporations who have worked or paid to possess it. For example, immense sums of money have been spent in exploration work by the great oil companies in all parts of the world: they tend to maintain a close secrecy over the results.

The surmounting of such difficulties is a major task of the Commission: the important point is that the resolution is a practical expression of the ideals of the democratic way of life. These are the ideals for which the British Empire is fighting, and the scientific workers of the Empire should surely associate themselves with the lead thus given by the American Scientific Congress. That the New World has initiated the move should not be a source of jealousy in the Old World torn by strife, but rather a source of inspiration that democracy is a living force with a plan for the future.

MOLECULAR SPECTRA AND MOLECULAR STRUCTURE

Molecular Spectra and Molecular Structure
1: Diatomic Molecules. By Prof. Gerhard Herzberg. Translated with the co-operation of the Author by Prof. J. W. T. Spinks. (Prentice-Hall Physics Series.) Pp. xxviii + 592. (New York: Prentice-Hall, Inc., 1939.) 6·50 dollars.

DURING the last two decades great progress has been made in the experimental study and theoretical interpretation of molecular spectra, which has thus become one of the most important means we have for investigating molecular structure. There is, indeed, no experimental method that gives more detailed information on this subject. From the spectra, the discrete energy states of the molecule, as well as the limits of energy continua, can be derived directly. From these in turn we can draw precise conclusions concerning the orbital motions of the electrons, and the vibrations and rotations of the nuclei. As to the electronic motion, we may learn its quantal type, including its symmetry and arrangement of nodes; we may deduce its energy as a function of the inter-nuclear distances, and its angular momentum; and we can evaluate any associated angular momentum due to an unbalanced relative orientation of electronic spins. This information has led to a deeper theoretical understanding of chemical bindings. As to nuclear vibrations, we can learn their frequencies, calculate the forces between the atoms, and derive also the energy required to bring about dissociation, as well as the dependence of the dipole moment and polarizability of the molecule on inter-nuclear separation. From rotational data we can derive very accurate values for the inter-nuclear distances, and in special cases obtain information concerning the spin and statistics of the nuclei. The detailed and quantitative knowledge of molecular constitution thus obtained leads, in its turn, to the possibility of calculating certain properties of matter in bulk ; for example, in the fields of magneto-chemistry and thermodynamics ; the total energy, free energy and specific heats of many gases can be derived more accurately from spectroscopic data than by direct thermal measurement. Other achievements of molecular spectroscopy in the chemical field include the detection and characterization of many molecules, radicals and ions, C_2, He_2, Na_2, OH, CP, H_2^+, HCl^+ and some hundreds of others that were not previously thought capable of free existence, the elucidation of elementary chemical reactions, and the prediction of chemical equilibria.

All this is so much in the spirit of modern physical chemistry, and yet so difficult a field for the novice to enter, that the appearance of a comprehensive text-book in English on the subject by Prof. Herzberg is an event of considerable importance. It will undoubtedly accelerate the future development of physical chemistry ; for there could be no better teacher of spectroscopy and its applications than Prof. Herzberg, and no better instrument for the translation of his writings than the collaboration of his colleague Prof. Spinks and himself. In the earlier book "Atomic Spectra and Atomic Structure", which was written and translated in the same manner, we became familiar with that singular clarity of style which makes learning a pastime and renders a comparatively short text both suitable to beginners and sufficiently comprehensive to assist the research worker. The new book, which is an extension of, and improvement upon, the original German text, has all the simplicity and crisp directness of the old ; and it goes definitely further in the direction of comprehensiveness. It deals only with diatomic molecules, but the author says in his preface that a further volume on polyatomic molecules "will follow as soon as possible."

In order to assist the beginner, certain sections of the text, which are not necessary for an understanding of the fundamentals, are printed in smaller (but not small) type ; while, for the sake of the research worker, an extensive bibliography is given, as well as a number of valuable tables, and diagrams to scale of energy levels and potential curves. One table gives the molecular constants for the ground states of all the diatomic molecules investigated up to July 1939. The research worker will also be glad to find descriptions of procedure, such as the procedure for analysing a band system, or an individual band, locating and identifying energy states, or tracing the potential energy curve for an excited state from intensity variations in continuous absorption. The very detailed subject index, which also contains all terms, symbols and quantum numbers, should be useful both to the beginner and the research worker.

As the author remarks, it is not possible nowadays to give a satisfactory presentation of the subject of molecular spectra and molecular structure without treating thoroughly, apart from the empirical results, the theoretical background also. He has therefore included as much of the theory of molecular spectra as is possible without complicated mathematics. This means, for example, that the general method of deriving selection rules is explained ; that all the selection rules which can thus be derived are stated ; but that the actual derivation of these rules is carried through only in a few cases, chosen for their mathematical simplicity. On the other hand, a large number of diagrams serve to illustrate and explain the theory, and throughout contact is kept, by the aid of numerous spectrograms, some taken specially for the purpose, with the experimental material that forms the basis of the subject.

The general plan of the book is as follows. A résumé of the elements of atomic structure is succeeded by a description of observed molecular spectra. There follows an account of rotational and vibrational, infra-red and Raman spectra. The main centre portion of the book is devoted to electronic band spectra, leading to the discussion of building-up principles, electron configurations, valency, dissociation, and pre-dissociation. A final chapter describes a number of applications of band spectroscopy to other fields of physics and chemistry, and to astronomy.

The congratulations and thanks of the scientific public are due, not only to the author and translator, but also to the editor of the series, Prof. E. U. Condon, and to the publishers, Messrs. Prentice Hall Inc. In reading the work for the purpose of improving a course of university lectures—more than a casual reading, that is to say—I have noticed very few misprints, none of them serious. The printing is excellent, and the numerous scale diagrams reveal a high standard of draughtsmanship. The paper throughout is so good as to be quite suitable for the spectrograms and diagrams, although many of these are peculiarly rich in detail ; thus the necessity for 'plates' is avoided, and the reader secures the advantage that the illustrations appear along with the text to which they relate.

Prof. Herzberg's book will be assured of a grateful reception, and we shall eagerly await the promised sequel on the spectroscopy of polyatomic molecules. C. K. INGOLD.

SAILING THE SKIES

Flight without Power

the Art of Gliding and Soaring. By Lewin B. Barringer. Pp. ix + 251. (New York and Chicago: Pitman Publishing Corporation; London: Sir Isaac Pitman and Sons, Ltd., 1940.) 17*s.* 6*d.* net.

THE title of this book is "Flight Without Power", but when Chapter vi has been read one comes to realize the tremendous sources of energy that are available to the pilot of soaring craft, and in fact this chapter, which is entitled "Soaring Meteorology", commences with the sentence, "The *power* required for soaring is not derived from any power plant carried by the craft, but has to be taken directly from the energies available in the atmosphere".

"Soaring Meteorology" is contributed by Dr. Karl O. Lange, an authority on the subject, and the chapter is dealt with first in this review, as it is certainly the 'kernel of the nut'. It is well written and is perhaps the most clear, concise and up-to-date exposition on the structure of the atmosphere that has yet been specifically written for the sky-sailing pilot.

When wind is forced to pass over a hill an up-current is provided, and this will support the comparatively lightly loaded glider having a sinking speed no greater, or less than, the upward component of the air, but the pilot is constrained to remain within a relatively small area if he is to retain his height. On the other hand, thermal up-currents are formed in wide distribution over the earth's surface, so that by making use of these the sailplane is free to move in any desired direction, and moreover much greater heights may be attained by this means. As a 'bubble' of hot air detaches itself from contact with the ground, it is caused to rise on account of its decreased density relative to the surrounding air and continues to rise, losing heat on its upward journey due to expansion, until it possesses no excess temperature. But the temperature of the air through which it rises also decreases with height and so tends to accentuate the temperature difference, and so increase the height to which the thermal climbs. This falling off of air temperature with height is known as 'lapse rate' and is of importance to the soaring pilot equal only to that of the wind velocity for the sailing boat. Dr. Lange shows that there are five possible standards of lapse rate, but for successful soaring flight the lapse rate must be unstable, that is to say, the air temperature must fall off by more than 1° C. per 100 metres, the amount by which the air 'bubble' temperature falls off with height. In a lower lapse rate it is obvious that the ascending current would soon lose its momentum and fade. The moisture, or water vapour, carried up in the thermal bubble condenses at a certain height (temperature), depending on the amount of vapour present, since the saturation capacity (dew point) of cold air is less than that of warm air. Thus the well-known cumulus clouds are formed, and they supply the pilot with sure signposts to the presence of ascending air currents. The chapter is well illustrated with cloud pictures and diagrams, and includes much useful information on how best to utilize the clouds and what types to treat with full respect.

The author of this volume is Lewin B. Barringer, one of America's foremost sail-plane pilots and the holder of the coveted 'Silver C'. Apart from considerable flying experience of both soaring and power aircraft, Mr. Barringer for some time managed the Wings Glider School, and therefore writes with knowledge of club organization and instruction. It might be more correct to refer to him as editor instead of author, for although seven of the twelve chapters are written by his pen, 122 of the 223 pages are contributed by others. Chapter i deals with the history of motorless flight and is written by N. H. Randers-Pehrson. "Aerodynamics", written by Paul Schweizer, is interesting and should prove useful, but it is rather slovenly put together and contains several mistakes (mostly careless typographical), and some of the symbols become changed as the chapter proceeds. Paul and Ernest Schweitzer contribute a lengthy chapter on "Design, Construction and Maintenance", but it is chiefly descriptive, and to some extent lacks 'meat'. It does, however, include some interesting details of the "Meise" sail-plane that was chosen as the standard design for the projected 1940 Olympic international competitions.

A brief, but somewhat sketchy, chapter by C. H. Colson is devoted to instruments. Certain basic principles, such as the measurement of air pressure by a Pitot tube, and the action of the gyroscope, are assumed to be known; but if such facts are known by the reader it is likely that a rough idea of the functioning of the various instruments is also known.

The author deals in Chapter iii with types of gliders. Launching methods are fully covered in Chapter v, much useful information being contained therein. "Towing Methods" are ably described in Chapter x, but the preference for automobile towing for training purposes, in place of winch towing favoured in Great Britain, is a little surprising. Chapter xi, on "Soaring Technique", based largely upon the author's own experiences, is full of interest. "Soaring Sites" and "Clubs" are the titles of the next two chapters, followed by the "Future of Gliding and Soaring", which but lightly touches on the future and is a trifle disappointing.

The book concludes with an appendix giving a list of soaring pilots, contest statistics and table of records, together with biographical sketches of the first ten American 'Silver C' pilots. A bibliography, glossary and index are also included.

In conclusion it can be said that "Flight Without Power" is essentially a book for the potential cross-country sail-plane pilot, and as such it can be recommended as one of the best volumes yet produced.

C. H. LATIMER-NEEDHAM.

THORPE'S "DICTIONARY"

Thorpe's Dictionary of Applied Chemistry
By Sir Jocelyn Field Thorpe and Dr. M. A. Whiteley. Fourth edition (revised and enlarged). Vol. 4: Digallic Acid—Feeding Stuffs. Pp. xxiii + 604. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1940.) 70*s*. net.

SINCE this section of the fourth edition was sent to press one of the editors, Sir Jocelyn Thorpe, has died. It is sincerely to be hoped that the remaining editor will be able to continue the work on her own or will be able to find someone to help her in the tremendous task of revision.

At this juncture it is opportune to direct attention to the format of the title-page. No indication is given therein of Sir Edward Thorpe's editorship of previous editions, nor of their dates, and the younger generation might well be excused for thinking that Sir Jocelyn Thorpe was responsible for them, whereas, in point of fact, there was no relationship between the two men.

The longest article in this section is by the late H. Shankster on explosives, in addition to one on dynamite. No cross-reference is given under nitro-hydrocarbons to "Benzene and its Homologues, Nitro Derivatives", in vol. 1. This omission is perhaps just as well, since the latter contains a drawing of a nitration plant which is certainly not used for explosives. Rumour has it that the plant was designed by a young man without experience in the subject, and the design was afterwards adopted in an emergency plant near London at the beginning of the War of 1914–18, only to result in the plant being blown up owing to faulty planning of the cooling coil which was inadequate to control the heat emitted by the reaction. Whether the rumour be false or only partially true, it does illustrate the fact that the utmost care is needed in the selection of contributors to ensure that the subject-matter is beyond reproach.

Previously, the subject of "Dyeing" and "Identification of Dyestuffs on Fabrics" were separate articles. These are now combined into one under the pen of Ellis Clayton, and "Dyestuffs, Azo", is by M. Lapworth.

Welcome additions, which were not in the previous edition, are well written, and include concise articles on "Industrial Dust", by J. A. Holden and "Dust Explosions", by T. N. Mason. It would have been interesting, however, if the section on the physiological effects had been expanded, especially as regards silicosis. For the safety of workers in the chemical industry, a dictionary such as this one can prove of inestimable help in providing ample and adequate information and reduce those casualties due mainly to lack of knowledge. In fact, any toxic chemical should have a section included on its physiological effects and means of overcoming them.

On the subject of distillation there is an article by J. Reilly and D. F. Kelly on laboratory practice, since the industrial aspect is being dealt with under the heading of "Stills". This article is mainly concerned with the physical chemistry of the subject and does not include the questions of number of theoretical plates and column liquid hold-up; the essentially practical aspect of the subject developed by Podbielniak and others is not mentioned. This is to be regretted, since the practice of laboratory distillation is often little understood by the majority of organic chemists.

"Emulsions and Emulsification" makes its first appearance, and includes line drawings of emulsifiers and a list of recent patents on the chemical side. It is by A. King.

The chemical engineering aspects are covered by "Drying", by S. G. M. Ure, "Evaporation", by J. A. Reavell, and "Extraction", by W. Peck. The article on drying is new, and is a valuable addition. It deals with the various commercial types of plant, which are illustrated in a clear manner, and convey the essentials at a glance. The references are comprehensive, and no doubt explain the absence of drying theory, which is still in a somewhat transitory state. The photographs in "Evaporation" do not convey much information and could be omitted; little is given on heat transmission and general theory, and no references are included to help the reader to find this information for himself. "Industrial Extraction Apparatus" contains much that is new, especially with reference to sugar beet. Here again, one of the photographs of a thickener could very well be dispensed with.

The general impression left by this volume is that the editors and contributors are to be congratulated on the excellence of their articles, and that if there is, here and there, some scope for criticism, it is almost unavoidable in a work of this nature.

ECONOMICS OF PRIVATE FORESTRY

Economics of Private Forestry
By Prof. Ralph W. Marquis. (American Forestry Series.) Pp. viii +219. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 18*s*.

THE forestry question is indisputably one of extreme importance in the United States, as the increasing number of books on the subject testify. Some of these have been published in the American Forestry Series of which Walter Mulford is consulting editor. One of the latest is a volume dealing with the economics of private forestry by Dr. Ralph W. Marquis, assistant professor of economics, University of Rochester, New York, which is original in treatment.

As the author states, he is not a professionally trained forester, and his economic views at times run counter to accepted dogmas of the latter. As this book well shows, and is apparently designed to show, the forestry problem in America is to some extent overshadowed by the lumber trade and its interests; a position which probably does not exist to the same degree elsewhere in the world with the exception of Canada. In Britain when we talk about private forestry we allude chiefly to the private landowner, for few public bodies (with a notable exception or two) have interested themselves in the matter.

A perusal of Dr. Marquis's book proves that he is envisaging the matter from the angle of private interests, such as the capital locked up in the lumber companies, the farmer's woodlots, etc. Owing to the serious decrease in the forests and their supplies in the country, due to the gigantic fellings often accompanied or succeeded by devastating fires of the last eight decades or so, serious attention is being given to the future of the lumbering business and the successful marketing of timber from privately owned forests. It may be pointed out that these present only one aspect of this great problem in the United States. The author writes: "Ever since the days when the first Colonists landed on American shores our forests have presented a problem, but the problem has not remained static. As the nation has developed and population has increased, as the forests have been cut down, as homes and factories have been built and farms developed, as all our social and economic relations have changed and become more complex, so has the problem of the proper treatment of our forest resources changed and become more complex."

To the forester this reasoning appears difficult to follow. Many countries in the world have been faced with, or are facing, similar experiences. It is no new problem to the forester; and it is difficult to see why it should prove one to the economist. Demand for forestry produce went up by leaps and bounds in the United States, and the forests provided for the demand and paid the price. What was once regarded as an inexhaustible capital has shown itself to be far otherwise. It is true, as Dr. Marquis says, that many statements have been made on this forest problem and many conflicting solutions offered. In a different degree and from somewhat different angles the same is true for the many types of forests within the confines of the British Empire, not excepting Great Britain. But the answers are broadly the same. What has been utilized or destroyed must be replaced. Capital will be required and perhaps some form of Government legislation, as the author suggests.

In the more undeveloped countries or in those where under the land tenure system in force the State is the greatest landowner, the latter will be the chief forest owner and manager. But in all highly developed States it is recognized that forestry is at its best when State, corporation, town, and even village, with the private landowner in addition, all take a hand in owning and maintaining the area of forest economically necessary for the requirements of that country—so far as these may be provided from the area available for this purpose. These are the broad principles. Dr. Marquis, in directing attention to existing private vested interests, appears inclined to consider that these latter should undertake the chief part in the forestry problem, the State serving as a benevolent godfather. But Prof. Westveld has shown that the National and States' forests already amount to an area of some 169 million acres, and that the former at least will be considerably increased from the area of approximately 432 million acres still in private ownership. It would appear that there is work for all categories of ownership, the central Government giving the lead.

E. P. STEBBING.

PSYCHOLOGY AND HUMAN VALUES

Nouveau traité de psychologie

Par Prof. Georges Dumas. Tome 6 : Les fonctions systématisés de la vie affective et de la vie active. Pp. 546 + iv. (Paris : Félix Alcan, 1939.) 125 francs.

THE topics dealt with in this volume lend themselves to lengthy and detailed discussion in separate essays, and adequate criticism would necessitate a study of each article in detail. In that case criticism would probably become controversy, since the writers are mostly concerned with highly theoretical issues. Let us say at once that it maintains the high standards of its predecessors alike in the style and quality of its contents and in the excellence of its production. Though the whole work has now grown to dimensions which cause the eyes of busy readers to turn affectionately to its two-volume predecessor, we hope that the remaining volumes will not be too long delayed by the War. Furthermore, it is surely in order to salute our French colleagues and to tender our sympathy and good wishes. The volume under review is a reminder of how much we owe to French psychologists ; probably it could have been produced in no other country. But let one of the volumes be an adequate index to the whole.

The present volume is very reminiscent of the psychological treatises of an earlier day, factual knowledge being less prominent than detailed theoretical discussion and criticism. It is richly informed by recent writings and amply documented ; but more note might have been taken of the work of the pioneers who have tried to break ground in these stubborn fields by experimental methods. A treatise of such scope is incomplete if it does not take full account of the work carried out by Americans in this field, even if the writers think that it only touches the fringe of the subject. English readers may think that less than justice is done to the views of McDougall and Spearman. The present writer believes that the future lies with those who follow the experimental path, even though the results are at present modest. When Prof. Delacroix boldly attacks "Les Sentiments esthétiques et l'Art" and "L'Invention et le Génie" the main result is to show how little can be said authoritatively on the greater values of human life. Nevertheless, a discussion of such problems is profitable when conducted with such clear common sense as the author brings to bear upon them. In fact, the volume is distinguished throughout for hard common sense and insight into the higher levels of man's emotional life. These qualities are shown in the acute criticisms of theories more pretentious than these writers are prepared to offer. While it may be thought that "L'Évolution, la Spiritualisation et la Socialisation des Tendances" are not yet ripe for strict scientific treatment, psychology will profit by the reminder that it has to take them up. The whole volume is a reminder that psychology deals with real and living human beings.

The qualities mentioned are well exemplified in the chapter devoted to volition (Ch. Blondel). The experimental work is fairly discussed and put on one side as unlikely to attain important results by reason of the triviality of the material used ; it is concerned with children's games rather than with true volition. The data secured are only made intelligible by a study of moral choice, thus reversing the intention of the researches. To this it may be replied that the triviality of the material employed in experimental researches does not make the results trivial. The students criticized would be content if they could claim that they had clearly demonstrated this or that feature of volition. Prof. Blondel is too exclusively concerned with moral choice. Not all volitions are on the heroic scale. Even the decision to buy a hat, or to call two spades, deserves analysis, and probably these simpler cases will reveal the central factors present in all volition. But, having entered this protest, we are free to enjoy the broad wisdom and humour of the author's treatment. Like his colleagues, he restores the balance which may be disturbed by deriving wider conclusions from experimental data than they really justify. In this chapter (as throughout the volume) emphasis is laid upon social factors, though much more analysis will be required before the appeal to them can be decisive for psychological theory.

A. W. P. WOLTERS.

SOME RECENT ADVANCES IN DAIRY SCIENCE[*]

BY PROF. H. D. KAY, O.B.E.
NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING, SHINFIELD

COMPOSITIONAL QUALITY OF MILK

ALTHOUGH many mammals other than the cow have been used by man for milk production—in Great Britain we have some 120,000 milking goats at present, and both here and elsewhere sheep, mares, asses, camels, buffalo and deer have been used for producing milk for human consumption—when we speak of milk we usually mean cows' milk.

In war-time, when our diet tends to be restricted directly or indirectly owing to enemy action, the place in the dietary of cows' milk, valuable as a source of vitamins, lime and animal protein, increases relatively in importance. Produced entirely at home and produced to an extent which is less dependent on imported foodstuffs than is usually realized (some 84 per cent of the food of the dairy herd is produced in Great Britain) cows' milk is undoubtedly one of the key food products the supply of which must be maintained by every means in our power. This has been consistently recognized by the Government, which places the dairy cow as '*farm animal, No.* 1', and hopes to be able to meet at least 90 per cent of its pre-war requirements of imported food by restricting the supply to animals of less immediate importance. A tight, well-thought-out rationing scheme is the only way to meet this priority with the minimum of hardship to feeders of other stock.

From the national point of view, and the consumers' point of view, in war-time or in peace-time, but particularly in war-time, there are two separable but related factors in the maintenance of the milk supply—volume and quality. Volume can be measured by the consumer, quality is less readily assessed. Since at present milk is sold entirely on a volume basis, it is not surprising that what concerns the farmer is mainly milk yield—how many gallons he can obtain from a given expenditure of time, labour and feeding-stuffs. But the purchaser of milk, both the milk manufacturer who intends to make cheese or butter from it, or to dry it, and the liquid consumer (though the latter usually does not realize it) are also concerned with milk quality and composition. The food value of the same volume of milk from different cows, or the same cow fed different foodstuffs, is not always the same, though it is true that the usual variation between one *normal* cow and another is not great. Our trouble at present is that too small a proportion of our cows are normal. In practice it is found that between one individual and another, and even between the mixed milk of one herd and that of another, there may be variations of real nutritional importance. Variations in the food value of the same volume of milk as great as 15–20 per cent or even more are not infrequent, though the appearance of the milk and its price to the buyer or the consumer may be the same.

TABLE 1.

LOSS OF GROSS NUTRITIONAL VALUE IN LOW-QUALITY MILK.

	Percentages			
	Fat	Non-fatty solids	Total solids	Water
Typical good herds	4·05	9·00	13·05	86·95
	3·75	8·95	12·70	87·30
	3·80	8·85	12·65	87·35
Poor herd	3·05	7·85	10·9	89·1
Poor individual cow	2·50	7·45	9·95	90·05
Loss in food value as between good and poor herd ..	about 30%	about 11%	about 24%	—

What are the causes of these variations ? Can they be controlled ? The organized farmers of the country have shown their anxiety to have these problems solved, and the manufacturers of milk, for obvious reasons, would prefer to have the milk reaching them of more uniformly satisfactory composition. It is a matter of national importance in peace-time, and in war-time of even greater importance to establish these causes, so that we can maintain our milk supply at the highest possible nutritional value.

As a result of extensive investigations during the past few years, the main causes are fairly clearly established, though control of these causes is not so far advanced as could be wished. The following are the main factors concerned, put in probable order of present importance. The relative importance varies from one season of the year to another, and probably from one year to another :

Udder disease, even in the sub-clinical stages.

Feeding of insufficient supplementary food, particularly in late summer, usually associated with drought.

Breed differences.

Physiological disturbances, unassociated with disease in the ordinary sense, probably due to hormone imbalance.

Adventitious watering.

---

[*] From a discourse delivered at the Royal Institution on November 19.

There are, of course, minor causes which affect individual cows—for example, end of lactation milk, which is often a little abnormal in composition—but the main causes of low-quality milk are undoubtedly those just mentioned.

Udder Disease. This is at present the principal cause of inferior quality milk. The chief trouble is mastitis—an inflammation of the udder which may vary from very mild to very severe in intensity, and is usually due to infection with a specific streptococcus, *Str. agalactiæ*. It is usually accepted that this particular organism is not pathogenic to the human consumer, even if he drinks the infected milk.

It has been known for a long time that mastitis diminishes milk quantity, and that severe or acute mastitis diminishes milk quality. The main addition to knowledge in the last few years is that udder infection of this type may affect compositional quality quite as seriously, and do so even before the diseased state of the udder becomes patent to the expert eye. In an investigation we carried out some three years ago extending over twenty-nine good commercial herds, mastitis infection was found on bacteriological examination in at least 61 per cent of the animals which yielded low quality milk. Practically all these cases were cases where the disease had not proceeded far enough to be obvious on expert examination of the udder, though a simple examination of the milk would have revealed many of them. It is now known that the test we employed misses quite a number of positive cases, though it does not show any false positives. Hence 61 per cent can be regarded as a minimum estimate; the truth will be nearer 80 per cent.

It has been calculated that mastitis causes a fall in our national milk yield of some 6–7 per cent. I am not too happy about the basis of this calculation, though I believe the result is not far from the truth. If we assume a loss of only 4 per cent in volume, the producers of Great Britain are losing not less than £2,500,000 each year as a result of this loss of milk. There is, in addition, the loss of milk *quality* and food value, so that our figure of £2,500,000 may be taken as a highly conservative estimate of what the nation is paying annually for this disease. We are spending less than £5,000 annually in research on methods of dealing with it.

In war-time this loss of milk and of food value is one we can particularly ill afford. Fortunately the researches of the past few years, parsimoniously supported though they have been, have yielded new information which shows that if a farmer is willing and financially able to take certain simple steps, he can achieve a great measure of control over the severity and spread of the disease in his herd. Though at present he cannot, unfortunately, eliminate it completely, he can, by the regular examination of milk from every quarter of each of his cows, using a simple method which can be carried out on the farm, followed by partial segregation of infected and suspected animals and veterinary help with the treatment of clinical cases, effectively control it, so that yield and quality of milk from his herd will steadily improve and eventually return to the normal. An essential part of the control scheme is the careful disinfection of udders, of milkers' hands, and of parts of milking machines that come in contact with the cow, with dilute hypochlorite solution. Another is the avoidance of rough handling, over-stocking and the misuse of milking machines.

Some of us think that now is the time to apply this knowledge on a national scale. It could scarcely fail to increase appreciably our milk supply, which at present, from a variety of causes, is tending to flag.

Poor Feeding. The feeding of insufficient concentrates has been clearly shown, by controlled examination of data during the last few years, to be another important factor in the production of poor quality milk. Such feeding also obviously affects milk yield. In war-time, with diminished supplies of imported concentrates, this difficulty is not easily overcome; but it must not be assumed that *imported* concentrates are the only foods which will help matters. Home-produced food, with a reasonably good protein content, or even good hay or silage, will help appreciably to maintain both yield and quality in conditions of drought. If more farmers had taken to heart the research findings of the last two decades in improvement of grassland, in the use of the plough on old pastures, in types of grasses to be grown and in methods of management of grassland, the stock-bearing and milk-producing capacity of large areas of Great Britain would have been greatly increased, and our dependence on imported concentrates diminished.

Breed of Cow. It is well known that normal cows of certain breeds such as Friesians and Shorthorns tend to give milk that is somewhat lower both in fat and non-fatty solids than cows of other breeds such as Guernseys or Jerseys, Ayrshires being intermediate.

Table 2.

Breed	Fat	Solids-not fat	Protein	Ash	Water
Jersey	5·1	9·6	3·8	0·75	85·3
Guernsey ..	5·0	9·55	3·8	0·75	85·5
Ayrshire ..	3·85	9·05	3·3	0·69	87·1
Shorthorn ..	3·6	8·95	3·3	0·73	87·4
Friesian	3·45	8·5	3·1	0·68	88·0

The average difference is not very great with typical healthy animals of the different breeds; but it is still quite appreciable, and a gallon of average Jersey milk undoubtedly contains more calories of food value than a gallon of average Friesian milk. On the other hand, the percentage variation in compositional quality of Jersey milk from one milking to another is greater than in the case of Shorthorn or Friesian milk.

Physiological Disturbances. It is now recognized that a number of cows which produce milk of low compositional quality are neither diseased nor insufficiently fed. Their milk may be well below the herd or breed average in composition, and may remain low from one lactation period to another.

In thinking over the various causes which are known to produce changes in the fat content of cows' milk, it occurred to us in 1931 that a rise in fat percentage frequently resulted when the *metabolic rate* of the cow was increased. Why not, therefore, find out whether small doses of thyroxine, the iodine-containing hormone of the thyroid gland which has the characteristic effect of increasing metabolic rate, would increase milk quality when given to a lactating cow ?

This experiment was first tried by feeding dried thyroid gland to lactating cows, and preliminary results were obtained showing a rise both in quality and quantity of milk. Eventually it was shown that if thyroxine were administered in small quantities daily to cows past the peak of lactation, both yield and quality of their milk were increased. There was in the milk more protein and lactose and milk fat, and less water. In some cows the daily yield of fat was increased by 40–50 per cent, so the results produced were not small. If, however, the thyroxine were administered before or at the peak of milk production, both milk volume and fat production were diminished.

Concomitant with the increase in milk quality, there was a rise in the speed of circulation of the blood, in the breathing-rate, and in the level of sugar in the arterial blood.

The improvement in milk quality *may* have been due to an increase in the blood sugar. It is known that the level of blood sugar decreases quite markedly whilst the blood is going through the udder, and there is some evidence that the larger the yield of milk, the more blood sugar is taken out of the same volume of the blood by the udder. It is an attractive hypothesis that the sugar-level in the blood reaching the mammary gland is one of the main factors in improving milk secretion. It is known that if the blood sugar is diminished, the amount of milk secreted in a given time is decreased, and also that the chemical quality of the milk produced is lowered.

Whatever the mode of action of thyroxine, there is no doubt of its potency in improving milk quality, and the question arises as to whether poor quality milk that cannot be ascribed to disease or faulty feeding of the cows is due to inherently poor thyroid secretion.

But the thyroid is not the only hormone concerned. It was found some ten years ago that an extract of the anterior portion of the pituitary gland will stimulate milk secretion in animals the mammary glands of which are fully developed but from which the ovaries have been removed. Later it was found that crude extracts of anterior pituitary gland would cause an increase in yield of milk and a slight rise in the percentage of fat in that milk if administered to normal cows in declining lactation. Purified extracts of this gland, containing very small amounts of solid matter, are also potent in this respect. The activity was at first ascribed to a single hormone of the pituitary which was called prolactin. Very recent work has gone to show that this activity is, in fact, due to the co-operation of two separate hormones of the anterior pituitary—prolactin and glycotropin. The whole story, in which the relationship of the pituitary hormones to thyroid gland stimulation is probably involved, is at present far from clear.

The matter is still further complicated by the discovery, made about four years ago, that a hormone of the ovary—œstrone—when administered to a cow in full lactation, causes a slight initial fall in milk yield, but a considerable increase in the proportion of non-fatty solids in the milk, an increase which may persist for weeks after the œstrone treatment has been discontinued and the initial slight fall in yield has worn off.

Though the general picture is only beginning to take shape, we now know of more than one glandular extract by the administration of which milk quality may be, in certain circumstances, improved. Other agents, some of them œstrogenic, as well as being relatively cheap and capable of chemical synthesis, are being tried, dosages and methods of administration compared, difficulties are being overcome, and in time methods of practical importance to the farmer in controlling and increasing udder efficiency will undoubtedly be evolved.

Adventitious Watering. The traditional association of the pump and the milk distributor is one of the three or four classical music-hall jokes. In fact, it is surprising how *little* water is put into milk, when one considers the difficulties of detection and the fact that milk is sold, under our present system, by volume and not by quality.

Methods for detecting added water have improved somewhat during the past few years. The ultimate criterion at present as to whether a given sample of milk is watered is by determination of the freezing-point of the milk. It will be remembered that the dissolving of even a small amount of salts or other small molecular solutes in water depresses the freezing-point below that of pure water to an extent which depends on the number of particles in a given volume of solution. It has been shown that fresh milk shows a practically constant depression of freezing-point (Δ) from one cow to another. If the milk is fresh, whether it is of low or high solids content, or comes from a cow which is healthy or diseased, it almost invariably has a Δ of between 0·530° C. and 0·555° C. Addition of water diminishes the Δ, that is, brings the freezing-point of the milk nearer to that of pure water, in proportion to the amount added, and it may be taken as certain that if the Δ of the mixed milk of a herd, or of a bottle even of pasteurized milk, is below 0·530° C., then water has got into it somehow. All we can then hope is that it is not dirty water.

Little or no variation is caused in this constant even by udder disease. While udder disease may cause a drop in total milk solids, and a rise in the proportion of water present, the diminution in the lactose and other characteristic milk constituents is osmotically balanced by an increase in the amount of sodium chloride, so that Δ remains the same. Pasteurization of the milk, or even boiling, has only a minute effect on Δ. If, however, the milk is kept for a while and bacterial growth sets in, the number of small molecules in the milk begins to increase and the Δ increases also.

(To be continued.)

GEOLOGY AND EARLY MAN

BY H. B. S. COOKE, PROF. C. VAN RIET LOWE AND L. H. WELLS,
UNIVERSITY OF THE WITWATERSRAND

THE recent contribution by T. T. Paterson[1] under the above title provides a welcome stimulus towards the general reconsideration of Quaternary events throughout the world, and towards the ultimate unification of our rather scattered knowledge. So wide a survey must inevitably provoke that discussion which Paterson invites in his concluding sentence. His contribution provides an admirable foundation, and should lead, as it has in the case of the present writers, to joint observations by local workers in the various areas and fields concerned. To deal fully with the many points raised would require much space, and as we are most closely concerned with Africa, and particularly with southern Africa, this discussion deals mainly with points relevant to this region.

In such a discussion it is inevitable that most attention is devoted to those topics upon which we differ from Paterson, those upon which we are in agreement with him being largely passed over. It is, in particular, most welcome to find that appreciation is at last given to Geikie's great work, which, though at one time discarded, has now been found to have a sound foundation and a wide application to the northern glaciations. We agree equally with the adoption of Haug's faunal definition of the base of the Pleistocene. Paterson's brief appraisal of the succession of Pleistocene faunal assemblages is also acceptable, and will probably prove to hold good broadly for Africa as well as for other parts of the world.

The geological correlations put forward by Paterson are of a controversial nature, but while the author's studies in India and elsewhere entitle his opinions to the most serious consideration, it would appear in general that the available evidence is inadequate for the conclusions outlined. Correlations within almost every region considered are still very uncertain. The glacial phenomena observed by Lee[2] in China still await detailed work and correlation with the sedimentary cycles; in the same country De Chardin and others are not yet decided upon the course of events; in India, Morris[3] has only recently brought forward evidence illustrative of the difficulties of *cis*-Indus and *trans*-Indus correlation; in northern Africa and in East Africa the sequence is only provisionally outlined, and in southern Africa there is as yet no evidence justifying correlation with other areas.

In the correlation given for the Vaal River Basin, the three phases of the Younger Gravels are indicated as spread over a period ranging from the bottom of the Middle to the lower division of the Upper Pleistocene, while the Older Gravels are placed in the upper portion of the Lower Pleistocene. It must be pointed out that the Older Gravels lie in terraces at elevations from 50 to 300 feet above the present river-level, whereas the Younger Gravels form a closely linked group at levels up to about 40 feet above the river. There is little doubt that the time occupied in the formation of the Older Gravels must have been considerable, and there is also evidence that a long interval separated their deposition from that of the Younger Gravels. The formation of the Younger Gravels cannot have occupied a comparable length of time, and the intervals between the three phases must have been geologically short.

I have recently been attempting to correlate the Quaternary geological events in southern Africa, and though many difficulties lie in the way of effecting correlations even in so small a region, it appears probable from geological and faunal evidence that the Younger Gravels are of Upper Middle Pleistocene age. The Older Gravels are provisionally referred to the Lower Pleistocene, though it is not impossible that they might even range in part into the Pliocene. As a result of this recent work I have also concluded that the grounds for correlation between southern and east Africa rest at present on too insecure a basis to be of much value. This does not, of course, imply that Paterson's correlations may not be largely applicable elsewhere where the evidence is perhaps more adequate, but at present the sequence in the Vaal River Basin cannot reasonably be interpreted in the manner suggested in that correlation.

There is now accumulating a considerable body of evidence to show that world-wide climatic changes occurred during the Pleistocene, and Paterson's observations on the possible cause of the Ice Age are extremely interesting. Daly had already largely established the simultaneity of glacial phenomena in the northern and southern hemispheres, and now Nilsson's[4] work in East Africa and Abyssinia shows almost conclusively that the Pleistocene climatic changes effected a reduction in the width of the equatorial belt and not the southerly shift advocated by Penck and others. Nilsson has also shown the apparent coincidence of glacial advance and "pluvial periods", which provides strong support for the theory that increased precipitation is accompanied by glacial advance. The theory advanced by Paterson would appear to fit in with these conditions and is thus of the greatest interest. Simpson's theory, however, which Paterson regards as the most acceptable, requires the production of two glacials corresponding to one major cycle of precipitation and consequently to only a single "pluvial" episode. On p. 14 of his account, Paterson remarks that the "major periods of aggradation follow on those erosional periods coincident with glacial advance" and this would not be true if a single "pluvial" represented two periods of glaciation. At present, therefore, the precise correspondence between glacials and "pluvials" cannot be regarded as established, and the basis for part of Paterson's correlations is thus very insecure. The effect of the Pleistocene climatic changes is very different in different regions, and the changes in precipitation in southern Africa appear to have been of a sufficiently low order to be readily masked by superimposed local phenomena. There is, nevertheless, a great deal of evidence in the northern hemisphere to encourage the correlation of glacial and periglacial phenomena there, and it should not be long before the extra-glacial regions can be fitted in with some degree of confidence. It is nevertheless felt that the geological correlation must be the foundation of comparison between scattered regions, and that this foundation cannot be established with sufficient confidence in the light of the present evidence. H. B. S. C.

In his contribution "Studies on the Ice Age in India and Associated Human Cultures" published last year[5], Paterson concluded his chapter on the prehistory of the Potwar and Indus regions with the statement that "further work is being carried out on new finds from the Punjab and the Madras palæolithic industries. Until this work is completed, it would be useless to attempt correlations or comparisons between northern and southern India". Following as this did on an unusually valuable description of the finds from eleven recently discovered palæolithic stations spread over an area of about 10,000 square miles in the basin or vicinity of the Soan River, one emerged from this first comprehensive contribution on the recent geology and prehistory of northern India with great hopes for the future of research in this field.

The outstanding contribution to our archæological knowledge was a detailed description of the Soan Culture originally noted by De Terra[6]. This new culture embodies a progressive series of pebble-and-flake industries spread over a long stratigraphic range. Comparisons could not reasonably be drawn between it (or any phase of it) and pebble, flake, or pebble-and-flake industries in other parts of the world. Yet within a year Paterson has attempted correlations and made comparisons not only between occurrences in northern and southern India but also between occurrences (both geological and archæological) in China, Java, north, central and southern Africa, Germany, France and North America, laying particular stress on the Soan Culture.

This culture is apparently based on eleven sites which yielded (*a*) pebble artefacts in certain cases, (*b*) pebble and Clacton-type flakes in some, and (*c*) pebble and Levallois-type cores and flakes in others—the whole representing five progressive divisions of the main culture. Only one "impure" site was found, namely, Chauntra. This yielded Soan tools together with elements of the hand-axe culture (? Abbevillian and Acheulean). He goes so far in his new paper as to assign the culture to a "genus" of the Clacton "family" and in it he recognizes half a dozen "species": the Kafuan-Oldowan of East and Central Africa, the pre-Stellenbosch and Stellenbosch I of South Africa, the Anyathian of Burma as well as certain industries discovered by Collins in Malaya, and others by von Koeningswald in Java.

While I wholeheartedly agree that the Lower Palæolithic nomenclature is rapidly approaching a state of complete chaos and that far too many prehistorians and Pleistocene geologists have made excessive and unwarranted use of certain French and Alpine terms, I do feel that in spite of ingenious three-dimensional charts, he has over-emphasized the Soan in relation to other known material cultures. He has built up his argument on far too few facts and has done little, if anything, to ease our present difficulties. The Soan is something new, as the Stellenbosch was new a few decades ago. We know far too little about it. Eleven sites are not enough—more especially when we recall the many thousands of palæolithic home and factory sites that have yielded pebble artefacts of Soan form in Africa alone. It is suggested that the time has not yet arrived when on such slender evidence we can emphasize and interpret this new culture in terms of occurrences at Clacton-on-Sea, on the Kafu in Uganda and along the Vaal in South Africa.

From my own experience in the field and museums of north, central, east and southern Africa, I can definitely say that the descriptions we have of the Soan do not justify our accepting Paterson's views of its importance in the Kafuan, Oldowan, pre-Stellenbosch and Stellenbosch I cultures of Africa. These pebble or core and core-cum-flake cultures certainly include some Early Soan *forms*, but so far as I am aware not one of them includes such significant cores as the distinctly Levallois types that occur in the Early Soan C, for example. We have flake artefacts in Kafuan, Oldowan, pre- and early Stellenbosch assemblages that recall or resemble certain Clacton forms, but none of them yet found is so advanced or sophisticated as the Early Soan specimens illustrated by Paterson. Despite the obvious mastery over the *bloc-en-bloc* anvil technique exhibited by Stone Age man during the Lower Palæolithic in Africa, we are not justified in correlating the cultures that include Clacton-like flakes in Africa with similar occurrences in Europe or India at this stage; or if we are, there would appear to me to be no reason why we should not rather emphasize the more fully described core-cum-flake Stellenbosch of the Cape. For years, for example, I have known the core-cum-flake biface (hand-axe and cleaver) industries of the Madras area to be mirror images of the Upper Stellenbosch of the Cape, which in turn is almost perfectly represented in the Upper African Acheulean of east-central Africa. I have often felt that if at this stage these Madras occurrences are to be given a name other than the helpful but rather loose southern Indian Acheulean, that name should be Indian Stellenbosch, but I have never felt justified in urging my point. Yet the evidence we have for such a comparison is based on much more substantial and widespread discoveries and data (geological and typological) than we have in the case of the comparisons Paterson has drawn.

I cannot escape the conviction that, on the evidence before us, Paterson's interpretations are premature and over-bold. Nevertheless I welcome his contribution, and sincerely trust that the discussions which are bound to follow will bring us a step nearer the solution of the most difficult problem that confronts the prehistorian of the present: the problem of comparison and correlation and the consequent need for a set of terms of wider application than those at present in use. Perhaps I should add that I have for a long time felt that prehistorians cannot hope to solve this major problem until Pleistocene geologists have reached an acceptable agreement on climatic correlations. Once we are able to correlate climatic events in India with climatic events in Africa or Europe or elsewhere, we can compare (1) the remains of human industry recovered from deposits related to these events, and (2) the products of human industry on the bases of typology and underlying processes.

In this way and in this way only, shall we learn whether the Soan of the Punjab is or is not older than the Clacton or Kafuan or pre-Stellenbosch, and so establish the genealogical and generic relationships that may exist between the products of human industry *where we have a sufficiently representative series of products* and allow for missing elements on worked sites. The much-needed new terminology will then emerge naturally. Until this fortunate state of affairs is reached I feel that so far as the Lower Palæolithic cultures are concerned it is better to struggle on (as we perforce must in the Upper Palæolithic) with such *local* terms as Clacton, Kafuan, Oldowan, Soan, etc., and where we can do so on such typological grounds as we have in the great hand-axe cultures, continue the more widespread yet tentative use of such established terms as Abbevillian and Acheulean, prefixing them where necessary with the words "African" or "Indian" as the case may be. In other words, let us for the moment recognize the Soan as something essentially north Indian, and limit the use of the term to India. C. v. R. L.

In the concluding section of his article Paterson treats of "The Development of Pleistocene Man". Herein he advances the conception of a subdivision of human types into three main stocks, Hominoid (Neanthropic), Palæanthropoid (Neanderthaloid) and Pithecanthropoid (including Sinanthropus). Each of these stocks, which it is considered should be given generic status, is supposed to be associated with a particular stream of development of Palæolithic culture. Moreover, as Paterson argues for the formation of mixed cultural groups by the fusion of these fundamental streams, so he presumes a corresponding mixture of the fundamental physical stocks to produce hybrid types.

There is undoubtedly much that is attractive in these views. Unfortunately, in their construction there seems to be insufficient differentiation between established facts and as yet unproved hypotheses. This is glaringly displayed in the opening sentence: "It is *already well established* (italics mine) "that Palæanthropoid man is associated with 'Levallois' culture, and '*Homo sapiens*', as distinct from '*Palæanthropus*' with the Acheul". While the first half of this statement may be substantiated, the second is supported by only the most tenuous evidence. Indeed, the only human fossil which is associated beyond doubt with the "Acheul" hand-axe culture is the Swanscombe skull, and the sapient or even proto-sapient character of this specimen cannot be regarded as proved, in view of the conclusion of the Swanscombe Committee[7]: ". . . it is necessary to admit that the missing parts of the Swanscombe skull may have been so formed as to provide clear evidence of differentiation from modern man." Paterson indeed assigns to his "Hominoid" stock the Piltdown skull, which is neither definitely associated with the great hand-axe culture nor indubitably proto-sapient in character, as well as a number of other specimens of debatable antiquity and associations.

Of these ascriptions the most provoking, to an African anthropologist, is the Kanjera material, the Acheulean associations of which Paterson is prepared to admit in spite of the objections of Boswell. This view may well be correct, although the history of the Olduvai skeleton urges caution. It brings in its train, however, a complication not hinted at by Paterson. Sir Arthur Keith[8] has described the Kanjera remains as "already endowed with features which definitely assign them to the African or Negro stock"; this judgment has been elaborated by Galloway[9], who has demonstrated in detail the affinities between the Kanjera remains and those from Boskop and elsewhere in South Africa. These remains, then, are not "Basic Mediterranean", as implied by Paterson, but in a broad sense "Negroid".

The "Negroid" type Paterson has proposed to derive from a fusion, as early as the middle Pleistocene, of "Hominoid" types practising a hand-axe culture with the "Pithecanthropoid" practitioners of a "Soan" culture. To this hybrid group he assigns Rhodesian man, remarking, at the same time, upon the resemblance of this type to *Homo soloensis*, which is conceived as the continuation of the unmodified Pithecanthropoid stock. Certainly, as has been repeatedly observed, Rhodesian man presents definite affinities to Pithecanthropus and Sinanthropus, as well as to the "Australoid" types of modern man. These indications are elucidated by material which Paterson has not considered, his only other reference to an African fossil type being to "*Africanthropus*" *njarasensis* of Weinert, which is in fact much too fragmentary for serious argument.

Paterson's most notable omission is the Florisbad skull, which is crucial in any interpretation of African types of man. Drennan[10], who in contrast to other South African investigators regards this skull as essentially Palæanthropoid in nature, nevertheless observes that "in Florisbad man, Rhodesian man, and the Cape Flats australoid skull we have a closely related phylogenetic sequence from Southern Africa linking the *Homo primigenius* to the *Homo sapiens* type". Dreyer[11] and Galloway[12], with Sir Arthur Keith[13], have considered the Florisbad skull to be at least proto-sapient and the precursor of later African types. This conception has been developed most elaborately by Galloway, who has shown that the Florisbad type links together the Rhodesian, Wadjak-Australian, and Boskop types. The last-named is clearly intimately related to the Bush-Hottentot group, and probably also to the true Negro, the Asselar skull described by Boule and Vallois forming a possible link between the Boskop type and the Negro. Thus Galloway has envisaged a scheme of relationships for the African and "Australoid" types not far different from that propounded by Paterson. It differs, however, in deriving this type not from a hybrid Hominoid-Pithecanthropoid ancestry, but from a single proto-sapient stock which could equally be the ancestor of the "Basic Mediterranean" and the rest of the sapient types.

Paterson's thesis is in fact an expression of the current tendency to an exaggerated polyphyletic conception of human evolution, though distinguished by his meritorious insistence on the possibility of hybridization as well as of independent evolution. It appears desirable to restate the simpler conception of Sinanthropus (whatever may be the relation of this type to Pithecanthropus) as a generalized as well as primitive human type which may well have given rise to both the Palæanthropic and Neanthropic stocks. Whether the differentiation of these stocks took place at the Sinanthropus level or, as is suggested by the Steinheim skull, not until a more advanced stage in development had been reached, is of minor importance. At every stage there must have been a great deal of variation around the periphery of every group. The scheme of relationships proposed by Dart[14] may with advantage be considered in this connexion.

The attempt to combine the discordant interests of polyphyly and hybridization with a formally binomial taxonomy raises in an acute form the problem of the zoological status and nomenclature of human types. Broom[15] has trenchantly criticized the arguments of Zuckerman on this question. Paterson's view, however, formally involves the hybridization of three genera belonging to two sub-families in order to give rise ultimately to a single species. Although the production of fertile offspring is no longer regarded as proof of specific identity, this is not altogether easy to visualize. Whether the problem needs to be solved by the drastic revision of our terminology advocated by Zuckerman remains to be seen. There is undoubtedly much to be said for Paterson's argument that man should be considered as a domesticated animal from this point of view, but the implications of this view demand careful examination.

In concluding this necessarily brief account, I wish to repeat on behalf of my co-workers and myself that our pre-occupation with those aspects of Paterson's comprehensive review which have struck us as particularly debatable does not imply any lack of appreciation of the value of his work as a whole. To have enumerated all the many topics upon which our views agree entirely with his has seemed unnecessary, and we feel that he is especially to be congratulated on his courage in advancing for discussion a thesis which another worker might have pondered but not ventured to publish. L. H. W.

BY T. T. PATERSON,

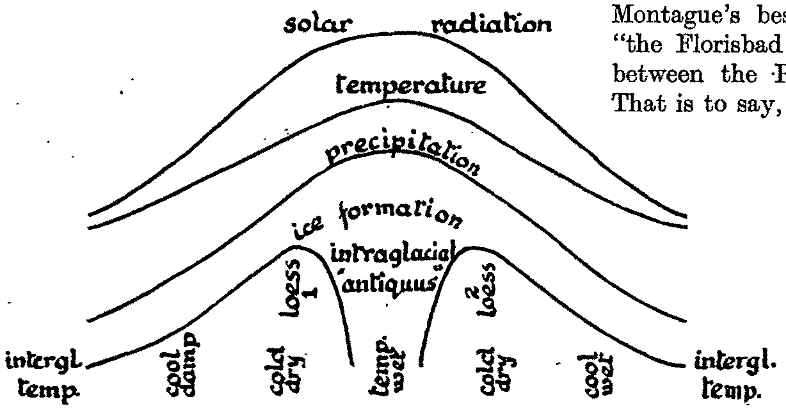
UNIVERSITY MUSEUM OF ARCHÆOLOGY AND ETHNOLOGY, CAMBRIDGE

These criticisms are welcome and helpful. In drawing up my Pleistocene correlation I first rejected the idea of glacial-pluvial correlation and began afresh constructing series of sedimentary cycles in tabular form. In areas where the sequence is complete seven cycles are present; in others some are missing, always the earlier. By comparing these tables with the three standards I adopted, those for Europe and India which I know well, and for China (I was assisted in this by Père Teilhard de Chardin), the correlation became obvious.

The Older Gravels of the Vaal River Basin may extend much farther back than phase I_2 but not later. The "long interval" referred to by Cooke, separating them from the Younger Gravels series, is reckoned on erosion depth and so surely depends on the intensity of erosion. A similar "long interval" of this age exists in almost every region. It is one of the stronger supports of my correlation. Moreover, if the faunal evidence suggests that the Younger Gravels are of "Upper Middle Pleistocene age", that is, I presume, on the faunal chronology of Hopwood, then there is nothing in this contrary to my proposition. I am unaware of the existence of a good fauna in the Vaal Basin.

In Simpson's theory the important point is his contention that *increase* in solar radiation produces glaciation; not decrease according to Croll's theory. But my application of Simpson's theory to the correlation which I found to occur, aguing to, not from the thesis of glacial-pluvial correlation, is a modified form of the theory. The curves here illustrate that modification. Thus in glacial and periglacial regions one cycle of solar radiation fluctuation produces two glacial pulsations during each glaciation and two terrace forms, while in non-glacial regions there is only one pluvial period and one terrace escarpment. Therefore, there must have been five major solar radiation cycles, reaching a maximum for the second glaciation and decreasing continuously thereafter.

Prof. van Riet Lowe's criticism deals essentially with nomenclature, though apparently he mistakenly believes that I think the Palæolithic exists in North America. "Further work," including another expedition to India by my colleague H. J. H. Drummond, revealed the Soan widespread in southern India. There are now more than thirty good sites known to us in the vast area that is India. The Soan technical tradition as I now see it extends from phase m_1 to u_3, from simple pebble tools + flakes, to pebbles + simple cores and flakes (Breckland types), to pebbles + cores and flakes (Moustierian types). Stellenbosch is a compound name indicating the presence, in South Africa, of two traditions, biface and core-flake-pebble (choppers) conjoined. If one or other of these traditions can be found separately over a long period then each deserves a tradition name, namely, Acheul and Soan. In South India, what I term Soan Acheul, or Acheulian Soan, could quite well be compounded into Stellenbosch and mean the same. If now in the earliest stages of the South African sequence, pre- and Stellenbosch I, only *one* tradition is found then a compound name cannot be applied, but only the single tradition name, and if these stages are core-flake-pebble comparable to the *earliest* stages of the Soan tradition, of the same age, then the latter name is justifiable. The Kafuan-Oldawan is more "pebbly" than the type Soan but within the range of variability of that technical tradition.



CLIMATIC CHANGES IN THE PERIGLACIAL REGION

If, as I believe I have demonstrated, the remains of human industry can be correlated geologically, then the attempt I make at determining the "genealogical and generic relationships" is profitable though it may not by any means be final. The "few facts" to which Prof. van Riet Lowe refers amount to several tons of rock in the Cambridge Museum.

The association, which I "glaringly" state, of proto-sapient and sapient forms with Acheul is based on my own practical experience of the conditions under which four crania have been found. The Swanscombe fragment, phase m_2, is one. Dr. Wells doubts whether I am justified in using this "unproved" evidence of sapient type, but on the other hand a very eminent authority has written castigating me for suggesting that Swanscombe man is anything but *Homo sapiens.* In the case of Piltdown man, depending upon the attitude of each individual researcher, it can be, or cannot be, regarded as proto-sapient; we have but to remember the controversy between Sir Arthur Smith Woodward and Sir Grafton Elliot Smith. For its geological horizon I follow Clement Reid, though I am well aware of Hopwood's opinion, and there is my own knowledge of extensive Lower Acheul occurrences within the gravels of the same age throughout southern England almost to the complete exclusion of others. The Bury St. Edmunds fragment, phase u_2, indubitably sapient, comes from a loam out of which Upper Acheul artifacts have been recovered. There are several sites around the same area where a similar loam yields a complete Upper Acheul industry. The Acheulian association of the Kanjera skull I am well prepared to admit, for I had the good fortune to be with Leakey in East Africa at the time of the controversy regarding this matter.

It is certainly reprehensible that I omitted Galloway's thesis on the relations of the Florisbad skull, but equally reprehensible is it that I did not mention Keith's ideas, Weidenreich's and Ashley-Montague's besides others. Quoting Galloway[1], "the Florisbad type [is] somewhere intermediate between the Rhodesian type and later types". That is to say, Rhodesian man is ancestral to the Negroid. The proto-sapient features of *rhodesiensis* are well enough known and Galloway goes on to say[3], after pointing out the close relationships of the Boskop type, *wadjakensis* and the Australoid, that the "Eyassi and Sinanthropus itself may well be variants of an early generalized type of which Rhodesian Man and Solo Man represent their respective modern recent descendants." The close generic relations of *soloensis* and *wadjakensis* are striking enough, hence these remarks support my proposition. The Florisbad type and *wadjakensis* are but derivatives of the hominoid-pithecanthropoid hybridism, the former towards the Negroid end, and the latter towards the Australoid end of the range of variability. I cannot deny, and make no pretence of doing so, that as a result of heterozygosis, and consequently greater variability within the proto-sapient stock, Kanjera may show Negroid affinities yet remain proto-sapient.

It is obvious that I am driving the hybrid horse rather hard, and this brings up Dr. Wells's last criticism regarding nomenclature. As Holmes[3] says, "few species of organisms present so great a variety of hereditarily diverse strains as our own". Hooton discovered a very fine specimen of a neanderthaloid "all-in wrestler" the other day in Boston, and it seems that the neanderthal type comes within the wide range of variability of the species *Homo sapiens.* I should hesitate long before suggesting that the pithecanthropoid is also a variety of the same species, but within the next order of difference it can be regarded as a different species of the same genus. That is to say, all those forms I discussed are species and varieties of the genus Homo. I can see, therefore, no objection to postulating hybridism, but like Zuckerman, I believe something must be done about nomenclature. To give an absolute classification, while regarding man as a domesticated animal, is not feasible, for then the wide variation of hominoid forms would demand for its setting out something like the Highland and Agricultural Society's Pedigree Book. I separate out these stocks as "genera", as I have indicated, because there is evidence outside the anatomy to support this first subdivision. Essentially they should be regarded as having at the most no more than specific differences. If I had suggested specific names then the classification of hybrid offspring of these stocks would have been as varieties at least, and the whole system would have become exceedingly clumsy.

I am grateful to Prof. D. A. E. Garrod for pointing out to me that Skhul man is not found with a hybrid culture.

OBITUARIES

Prof. H. J. Spooner

WE regret to record the death of Prof. Henry John Spooner, former head of the School of Engineering at the Polytechnic, Regent Street, London, on December 16, at the age of eighty-four. Born on June 16, 1856, he received his training at the Royal School of Mines, and was first associated with the Polytechnic in 1882, when the first series of lectures on engineering subjects was given by him. He was appointed head of the School of Engineering on its formation in 1886, a post which he held until his retirement in 1922.

He also practised as a consulting engineer, and took out a number of patents dealing with steam and internal combustion engines. He was one of the pioneer motorists, took a great interest in the early development of the aeroplane, was a great advocate of the elimination of noise, and was also intimately connected with the development of time-motion studies, for the purpose of improving the efficiency of various operations. He was also the author of a number of engineering text-books, and many thousands of students passed through his hands.

During the War of 1914–18, large numbers of workers of both sexes underwent intensive courses of instruction under his supervision, and he was also honorary technical adviser to the King George Hospital and to the Union of South Africa in connexion with vocational training at the military hospital in Richmond Park.

He was a member of the Institution of Mechanical Engineers, an associate member of the Institution of Civil Engineers, a member of the Institution of Automobile Engineers, and a fellow of the Geological Society, in addition to several other engineering and scientific bodies. In 1895 he became a Knight Commander of the Royal Order of St. Sava, Serbia, and in 1907 he became a knight of the Golden Cross of the Redeemer, Greece. P. KEMP.

Prof. M. Askanazy

PROF. MAX ASKANAZY, a leading Swiss pathologist, whose death has recently been announced (*Schweiz. med. Doct.*, 70, 1072; 1940), was born at Stallupönen in East Prussia on February 24, 1865. He studied medicine at Königsberg, where he qualified in 1890, and from then until 1895 served as assistant in the Pathological Institute. In 1894 he became lecturer in general pathology, pathological mycology and morbid anatomy, obtaining the title of professor in 1903. Two years later he was appointed professor of general pathology at Geneva. The high esteem in which he was held by his pupils and friends was shown on the occasion of his sixtieth birthday in 1925, when they dedicated to him a *Festschrift* which formed part of the 254th volume of *Virchow's Archiv*. His investigations occupied a wide field, but he devoted himself mainly to a study of the hæmopoietic system, animal parasites, and experimental and spontaneous tumours in man. His chief publications were "Dermoid Cysts of the Ovary" (1905), "Bone-marrow" (1927), and "Inflammation" (1929).

The honours conferred upon him included the Marcel-Benoist Prize in 1936, the freedom of the city of Geneva, and the honorary doctorate of the Universities of Coimbra and Geneva.

He died shortly after his seventy-fifth birthday.

J. D. ROLLESTON.

WE regret to announce the following deaths:

M. Henri Bergson, the celebrated French philosopher, on January 6, aged eighty-two (see also NATURE of January 4, p. 24).

Prof. Raymond Pearl, professor of biology in the School of Hygiene and Public Health, Johns Hopkins University, aged sixty.

Major L. C. D. Ryder, a member of the British Graham Land Expedition, 1935–37, reported killed in action, aged thirty-nine.

NEWS AND VIEWS

Major-General Iven Mackay, C.M.G.

THE mantle of General Monash, the Australian civil engineer who proved to be the greatest military leader of the Australian Imperial Forces during the War of 1914–18, has fallen on another man of science, Major-General Iven Mackay, who is in command of the A.I.F. now operating in Libya which recently took a leading part in the successful attack on Bardia. Mackay was assistant lecturer and demonstrator in physics in the University of Sydney in 1910, where he had obtained his 'blue' for rowing and for football; he combined his aptitude for sport with his scientific training by acting as sports as well as science master in the Sydney Church of England Grammar School during 1905–10. When he joined the staff of the Physics Department of the University of Sydney he also became a sports coach. Later he undertook the duties of student adviser. He worked in the Cavendish Laboratory during 1919. In 1933, he became head master of Cranbrook School, Sydney, and held that position until 1940. During his early career at the University thirty-six years ago he, together with several others, organized the Sydney University Scouts, which eventually formed the nucleus of the New South Wales sector of the A.I.F. Mackay was born on April 7, 1882, the son of a Scottish father and a Canadian mother.

New Year Honours List

THE names of the following scientific men and others associated with scientific work appear in the New Year Honours List: *O.M.:* Prof. Gilbert Murray, F.B.A., trustee of the British Museum and president of the International Committee for Intellectual Co-operation. *Baronets:* Sir Kenneth Lee, lately director general and secretary of the Ministry of Information, formerly chairman of the Industrial Grants Committee of the Department of Scientific and Industrial Research; Mr. Hugh Lett, president of the Royal College of Surgeons. *K.C.B.:* Dr. E. V. Appleton, F.R.S., secretary of the Department of Scientific and Industrial Research. *K.B.E.:* Mr. D. E. Vandepeer, second secretary, Ministry of Agriculture and Fisheries. *Knights Bachelor:* Khan Bahadur Maulvi Azizul Haque, Vice-Chancellor, University of Calcutta; Dr. S. S. Bhatnagar, director of industrial development, Advisory Board of Scientific and Industrial Research, and lately director of the University Chemical Laboratories, Lahore; Prof. W. L. Bragg, F.R.S., Cavendish professor of experimental physics in the University of Cambridge (who is taking the style Sir Lawrence Bragg); Brevet Colonel R. N. Chopra, professor of pharmacology and director of the School of Tropical Medicine, Calcutta; Mr. R. B. Ewbank, lately Commissioner for Natural Resources, Newfoundland; Dr. James Weir French, chairman of Messrs. Barr and Stroud, Ltd.; Mr. P. R. Laird, secretary, Department of Agriculture for Scotland; Brigadier C. G. Lewis, surveyor-general of India; Prof. J. S. E. Townsend, F.R.S., Wykeham professor of physics in the University of Oxford; Prof. R. S. Wallace, Vice-Chancellor, University of Sydney.

C.B.: Mr. J. S. Pringle, director of electrical engineering, Admiralty; Mr. R. A. Watson Watt, scientific adviser on telecommunications, Ministry of Aircraft Production. *C.M.G.:* Mr. C. Bullock, secretary for native affairs, chief native commissioner and director of native development, S. Rhodesia; Prof. R. T. Leiper, F.R.S., professor of helminthology in the University of London and a director of the Department of Parasitology, London School of Hygiene and Tropical Medicine; Mr. J. R. Mackie, director of agriculture, Nigeria. *C.I.E.:* Prof. H. G. Champion, professor of forestry in the University of Oxford, lately conservator of forests, United Provinces; Mr. C. G. M. Mackarness, conservator of forests, Assam; Lieut.-Colonel H. E. Short, director of the King Institute, Guindy, Madras; Mr. C. C. Wilson, chief conservator of forests (retired), Madras. *C.B.E.:* Mr. G. E. Bailey, managing director of Messrs. Metropolitan-Vickers Electrical Company, Ltd.; Mr. R. T. G. French, secretary of the Electricity Commission; Mr. G. Hogarth, fisheries secretary, Scottish Home Department; Lieut.-Colonel C. A. MacLean, cane commissioner, Bihar; Mr. W. E. Nicholson, director of education, Sierra Leone.

O.B.E.: Sukumar Basu, secretary of the Imperial Council of Agricultural Research; Mr. R. S. Browne, deputy conservator of forests, Madras; Major D. R. Crone, superintendent of the Survey of India; Mr. R. M. Drake, secretary of the Association of British Chemical Manufacturers; Mr. J. R. Haddow, veterinary research officer-in-charge of serology, Izatnagar; Mr. A. G. Herbert, secretary of the Forestry Commission; Mr. C. Hollyoak, superintendent of the Royal Ordnance Factory, Not[illegible]ngham; Mr. F. G. L. Holland, director of [illegible], Gilbert and Ellice Islands Colony; Dr[illegible]ck, director of agriculture, Fiji; Dr. [illegible]ns, marine superintendent of the Lan[illegible]estern Sea Fisheries Committee; Mr. [illegible]th, principal of the Presidency Coll[illegible]r. G. F. Masters, superintendent o[illegible]d Carriage Factory, Royal Ordnance [illegible]ch; Mr. J. W. Mills, deputy director [illegible]uction, Ministry of Aircraft Pro[illegible]ytton, chief livestock office[illegible]re and Fisheries; Mr. J. Ta[illegible] Ministry of Agriculture, [illegible]: Prof. Ananta Prashad [illegible] professor [illegible] Sanskrit, Patna College, [illegible] A. J. Noronha, lecturer in bacteriology [illegible]ology, B. J. Medical School, Poona, Bombay [illegible]f. Cumbakonam Kailasa Krishnaswami Pillai, professor of geology, Presidency College, Madras; Tufail Muhammad Chhaju Khan

Rajput, criminal tribes settlement officer and personal assistant to the collector of Sukkur, Sind; Raj Narain Singh, deputy conservator of forests, Utilization Division, Naini Tal, United Provinces; Dr. Raghunath Sabajirao Tiradkar, professor of medicine, Grant Medical College, and honorary physician, J. J. Hospital, Bombay.

Prof. A. F. Joffe: Award of Order of Lenin

FOR his outstanding work in physics, Prof. A. F. Joffe has been awarded the Order of Lenin, the highest honour in the Soviet Union. The award was made on the occasion of Prof. Joffe's sixtieth birthday. Prof. Joffe's study of the mechanical and electrical properties of crystals has gained him a world-wide reputation. His work on the photoelectric effect and the magnetic field of projectiles is of importance; during the past few years he has investigated semi-conductors. Under the guidance of Prof. Joffe, experiments have been carried out as a result of which it has been possible to increase the frost-resistance of Soviet-grown caoutchouc and to work out a new method for the manufacture of plastic synthetic rubber. He was responsible for the establishment of the Physico-Technical Institute in Leningrad in 1918, the first of a system of physico-technical and physico-chemical institutes in the Soviet Union in Kharkov, Dniepropetrovsk, Sverdlovsk, Tomsk, and elsewhere. Prof. Joffe is a member of the Academy of Sciences of the U.S.S.R. and also of many scientific academies of other countries.

Air Raid Damage at the Royal Observatory, Greenwich

THOUGH parts of the Royal Observatory, Greenwich, have been damaged on several occasions during recent air raids, the historic Wren building of 1675 remains substantially undamaged and the damage to instrumental equipment has been of a minor nature. The south portico of the Altazimuth pavilion was hit by a high explosive bomb and partly demolished. The Altazimuth instrument had recently been dismantled and a small reversible transit instrument mounted in its place; this was thrown from its mounting and broken in two, but the object glass and impersonal micrometer were undamaged. A personal equation machine had been fitted to the collimator in the south portico; this and the collimator-objective sustained no damage. Though the main gates were destroyed, the Shepherd 24-hour electric clock, well known to visitors to the Observatory, received only slight damage. The damage to the coverings of the domes has been considerable, but the objectives and mirrors of the principal telescopes, with other valuable equipment, were dismounted and sent away for safety in the early days of the war. The main building, erected at the end of the last century, has received minor damage. The time service provided by the Observatory has been maintained without interruption; alternative arrangements had been made early in the War to ensure its continuance in the event of damage to the Observatory.

Air Raid Damage at the University of Liverpool

THE buildings of the University of Liverpool have been damaged during air raids. One of the chemical departments in the main University buildings received a direct hit, and extensive damage was done in the laboratory, generating and battery rooms: damage to the structure of the building, however, was superficial. Nevertheless, the building was severely rocked and many of the laboratory instruments were affected; the building was not in use at the time and there were no casualties. More than a hundred windows in the University buildings, and particularly the Engineering Laboratories, have been destroyed by blast. Bombs have also fallen in the grounds of both of the University's halls of residence; the damage, however, was slight, consisting mainly of shattered windows.

A Committee on Reconstruction

IT is announced that the Minister without Portfolio, Mr. Arthur Greenwood, has undertaken responsibility for the study of reconstruction and post-war problems. Later on, when the end of the War can be more clearly foreseen, a Ministry will be formed for this purpose. Meanwhile, Mr. Arthur Greenwood will be chairman of a group of Ministers studying these problems. The object will be to find practical solutions for the immediate problems of a transition from war to peace, and also to outline and presently to amplify a policy for the years immediately following the War which will command the support of the nation as a whole and enable united action to proceed in peace as in war.

Medical Planning Commission

A MEDICAL Planning Commission has been set up by the British Medical Association "to study war-time developments and their effects on the country's medical services, both present and future". It will consist of 68 doctors, representing all branches of the profession, under the presidency of Colonel Thomas Fraser, consulting physician to the Aberdeen Royal Infirmary. The detailed work of the Commission will be undertaken in committees and sub-committees. The chairman of the council will be Mr. H. S. Souttar, surgeon to the London Hospital.

The Universities: An American Tribute

YALE and Harvard Universities have sent a telegram to the Universities of Oxford and Cambridge conveying a tribute to the "dynamic courage of Great Britain" and stating that an important aspect of that courage is expressed "in the determination of your scholars to pursue their researches in the spirit of Milton's Seraph, 'Unshaken, unseduced, unterrified'". The Vice-Chancellors of Oxford and Cambridge have replied, sending "grateful acknowledgments to Harvard and Yale for their tribute to the resolution of this country". They go on to say: "The cause of liberty and learning, now eclipsed over most of Europe, is nowhere better understood than in the great and historic institutions from which these Christmas greetings come. The more profoundly do we appreciate their noble and moving recognition of our endeavour, together with the other Universities of Great Britain, to maintain the continuity of scholarship and to keep, even in these days, the standards of knowledge unimpaired and the sources of truth unsoiled."

University of London Certificate in Natural History

JUST before the outbreak of war, the University of London, in response to an expressed demand, instituted a Certificate of Proficiency in Natural History, designed for teachers who require an additional qualification testifying that they have a practical working knowledge of natural history such as will be of special value in teaching it to children up to the age of fifteen. The necessary studies involved attendance at a course of lectures and laboratory work of about three hundred hours' duration, together with a certain amount of organized field-work. Considerable interest was shown in the University's new departure, and some education authorities were prepared to arrange suitable courses: but the dislocation of the school teaching services all over the country has brought about the result that the courses of study contemplated by the University are not suited to the present-day circumstances of teachers.

Consideration has therefore been given to the possibility of devising some special emergency regulations which would meet the intention of the original requirements and make the best use of the fact that large numbers of urban schools are now located in the country or at the seaside, and so presented with an opportunity of natural history study in the field which, under normal peace-time conditions, would have been impossible; as a result emergency regulations have been drafted. The main principles of the proposed new regulations are: (*a*) to substitute for the present lecture-laboratory requirement a directed course of private reading together with attendance at a fortnight's summer vacation course arranged by the University, and (*b*) to take advantage of the teacher's probable extended period of residence in rural conditions by putting the main emphasis on the work in the field, involving the writing under expert advice of a substantial essay on some specialized topic chosen by the student. At the moment, however, the University has no evidence as to how far such a scheme would be welcomed by those teachers who might have been expected under normal conditions to have studied for the original Certificate. Any teacher, therefore, who is interested in the proposed new scheme as outlined is invited to communicate with the University Extension Registrar, University of London, at Royal Holloway College, Englefield Green, Surrey.

A War-Time Formulary

IN view of the urgent need for a comprehensive war-time formulary for the guidance of medical prescribers, it is satisfactory to learn that, at the instigation of the Ministry of Health, a strong and representative committee has been set up for the purpose of providing such a formulary for use during the emergency. The following bodies have been invited to appoint representatives: the Royal College of Physicians, the Pharmacopœia Commission, the British Medical Association, the Pharmaceutical Society, the National Pharmacists Union and the Wholesale Drug Trade Association. It is understood that the Committee intends to complete its work as speedily as possible. The publication of this formulary will be welcomed by medical men and dispensers, who are at present without an official guide as to the best substitutes for drugs which are now almost unobtainable and the best methods of compounding them for administration to patients. Apart from the few additions to the monographs of the British Pharmacopœia and alterations of a few monographs and lists of scarce drugs and suggested substitutes prepared by the Medical Research Council, no attempt has hitherto been made to compile a comprehensive book of formulæ for use during the period of emergency.

New Winter Forage Grasses

WINTER forage in Great Britain is a matter of first importance to the farmer and any new methods of ensuring a supply are worthy of careful consideration. W. Davis has brought forward the suggestion (*Emp. J. Agric.*, 8, 289; 1940) that pampas and tussac grasses, although exotic species, might profitably be grown for this purpose. Pampas grass (*Cortaderia selloana*) is a common ornamental plant in Britain, and though its leaves are coarse and harsh, it appears to be surprisingly palatable. It is both winter green and able to withstand drought, so that it would be productive just when other pasturage is short, and further, its tussock-forming habit would be specially valuable on hill pastures during periods of snow. The use of pampas grass has recently been investigated in New Zealand, where the results are promising.

Establishment from seed is slow, and it is probably best raised under nursery conditions and not grazed for at least a year. Chemical analyses show that it is considerably less nutritive than clover or young grass, but its relatively high yield (50 tons per acre per annum) and the fact that it is consumed *in situ*, thus avoiding labour costs, are compensating features. Tussac grass (*Poa flabellata*) is a much-prized forage plant in the Falkland Islands. Like pampas grass it is slow to establish, but once the initial stand is secured, the crop should go on indefinitely. In its natural habitat (the sea coast), this grass shelters numerous birds and seals, whose trampling and scratching cultivates the soil, while their excreta act as manure; inland the domestic fowl serves the same purpose. This combination of plant and animal life appears to be of fundamental importance to the healthy maintenance of the tussac plant. There seems no reason why these two grasses should not flourish in Great Britain, and both would probably merit a trial, as they would prove a valuable asset when the usual types of winter feed are scarce.

The Commonwealth Solar Observatory, Canberra

THE first report of the present Director of the Mt. Stromlo Observatory refers to the period May 1939–April 1940, though it also sketches the history of the Observatory since its establishment in 1910, and gives a brief account of the main observational programmes carried out since the first Director's appointment in 1924. The observations of solar radiation begun in 1926 have been completed, and a discussion of the results is promised. One of the most interesting conclusions is that the correlation between total solar radiation and duration of bright sunshine is so close as to be useful for derivation of the first quantity, the direct observation of which is difficult, from the second, which is a standard meteorological datum. Spectrohelioscopic and visual observations of the sun have been directed respectively to the detection and mapping of bright solar eruptions, several spectrograms of which have been obtained during 1939. As compared with flash spectra, these show a puzzling enhancement of low-excitation Fe I and Fe II lines.

A new programme of stellar observations is planned for the Reynolds 30-inch reflector which has been converted from Newtonian to Cassegrain form for the purpose. A single-prism spectrograph for spectroscopic parallaxes and a photo-electric photometer have been made for use at the Cassegrain focus. The work on cosmic radiation and atmospheric physics with which the name of the Observatory is especially associated has been carried on with a few modifications, chief among which are the discontinuance of the observations of atmospheric electricity and night-sky luminosity, and an extension of the work on cosmic rays and the ozone content of the atmosphere. With the establishment five miles away of an official Commonwealth meteorological station, many of the routine meteorological observations have been discontinued, though measurements having a direct bearing on other Observatory programmes are still being carried out. An impressive list of papers published during the year shows that the establishment is more than maintaining its high standing amongst southern hemisphere observatories.

New Russian Botanical Gardens

NEW botanical gardens, attached to the Armenian Branch of the Academy of Sciences of the U.S.S.R., were recently opened in Erivan, capital of the Soviet republic of Armenia. The gardens, which have some three thousand species of plants, have grown up during the course of five years on the dry, stony, desert soil between the settlements of Avan and Kanaker, near Erivan, which has been reclaimed. One of the most interesting departments of the gardens is the section devoted to the plants of Armenia. Ultimately, some 2,600 specimens of the flora of this republic will be collected there; the section already has 350 specimens. In the centre of this section has been built a pond, resembling the high mountain lake of Sevan. In the pond have been planted specimens of water plants of Armenia.. In the southern part of the gardens the Geographical Department is concentrated. More than half the area of the gardens is occupied by arboreal plants. The flower gardens are exceptionally rich; in the Avenue of Roses and Fountains more than a hundred varieties of roses have been planted.

Health in Sierra Leone

IN the latest annual report of the medical services of Sierra Leone, the director, Dr. W. P. H. Lightbody records a satisfactory state of general health among a population of about 100,000 and an absence of major epidemics. Nutrition in the undisturbed tribal communities is fairly satisfactory, but in Freetown, the capital, with a population of 55,000, and the adjacent villages there is some evidence of qualitative defects in diet, mainly an insufficiency of protein. Among the 250 European officials resident, the average annual sick leave per resident was 6·46 days, almost exactly the same as that of the 1,000 African officials. Only 3 European officials were invalided home during the year. Among the 495 European non-official residents the total number who went on sick leave was 73. The most frequent causes of death among the population in Freetown was malaria, which causes nearly twice as many deaths as tuberculosis, the second largest cause of mortality. Malaria also accounts for 43 per cent of the hospital cases in the colony.

The Wellcome Foundation Ltd.: Appointments

DR. R. A. O'BRIEN, who joined the staff of the Wellcome Physiological Research Laboratories at Beckenham in 1910 and became director in 1914, retired at the end of 1940. Dr. J. W. Trevan, who became head of the Pharmacological Section in 1920, has been appointed to succeed him. Dr. S. Smith, head of the Experimental Research Department and manager of the Wellcome Chemical Works at Dartford, has been appointed director of the Wellcome Chemical Research Laboratories at Beckenham. Dr. W. M. Duffin has also been transferred from Dartford to Beckenham. Mr. J. Russell has been appointed manager of the Wellcome Chemical Works. Mr. R. L. Grant has been appointed head of the Chemical Manufacturing Department on the retirement of Mr. W. Taylor.

Announcements

MR. AXEL L. WENNER-GREN, a Swedish industrialist, has given a cheque for ten thousand dollars to the University of Toronto for the extension of the work of its Geophysics Department.

THE following vital statistics for Scotland for the quarter ending June 30, 1940, have been published by the Registrar-General: The birth-rate was 18·6, the lowest ever recorded for the second quarter of any year since the institution of national registration in Scotland; the death rate was 12·8, and the infantile mortality 67, which is 1 below the average for second quarters of the year.

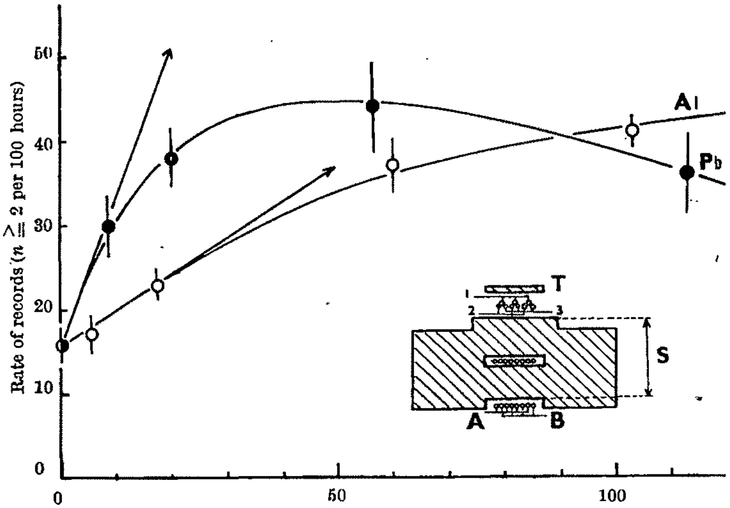
LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Penetrating Cosmic Ray Showers

IN a recent communication[1] we gave some evidence for the existence of penetrating showers. We have now extended these observations to the transition curves of the showers in lead and in aluminium with the same experimental arrangement. Five-fold coincidences 1, 2, 3, A, B, and the number (n) of the counters H discharged simultaneously were recorded. Due to a slight change in the counter arrangement, our present rates are about 30 per cent higher than those reported previously. The results are summarized in Table 1 and the accompanying graph.



TRANSITION EFFECT OF PENETRATING COSMIC RAY SHOWERS IN LEAD AND ALUMINIUM. INSET, THE EXPERIMENTAL ARRANGEMENT

As before, it will be assumed that only the records with n greater than or equal to 2 represent genuine penetrating showers.

The initial slopes of the transition curves are significant for the cross-sections for shower production. It appears that the observed ratio of the slopes of the lead and aluminium curves is the same, within the experimental error, as the ratio of the corresponding cross-sections for the production of electron pairs by high-energy photons. The arrows drawn in the graph represent slopes having this ratio. The comparison of the lead and aluminium transition curves suggests therefore two possibilities. The first is that these showers are cascade showers. As pointed out before[1], this assumption implies the breakdown of the cascade theory for high-energy photons and electrons. The second is that the showers are due to meson pair production or a related process.

Experimental evidence for the occurrence of meson pairs has been obtained from cloud-chamber photographs by Herzog[2] and Powell[3]. Meson pairs seem, however, to occur rather infrequently, and it is doubtful whether or not they can account for the observed rate of penetrating showers.

TABLE 1.

T (cm. gm./cm.²)		Material	Rates per 100 hour	
			$n = 0-8$	$n \geqq 2$
0	Light roof only		$56 + 4$	16 ± 2
0·8	8·5	Lead	89 ± 6	$30 \pm 3{\cdot}5$
1·8	20·0		127 ± 6	$38 \pm 3{\cdot}5$
5·0	56·5		99 ± 8	$44 \pm 5{\cdot}5$
10·0	113·0		104 ± 9	36 ± 5
2·0	5·4	Aluminium	$73 \pm 5{\cdot}5$	$17 \pm 2{\cdot}5$
6·5	17·5		91 ± 5	23 ± 2
22·0	60		115 ± 6	$37 \pm 3{\cdot}5$
38·0	103		$136 \pm 5{\cdot}5$	41 ± 3

The theoretical cross-section for meson pair production by a photon of energy $\hbar\nu$ is, according to Booth and Wilson[4],

$$\underline{\Phi}\ \text{meson pair} = \frac{5}{9}\,\frac{e^2}{\hbar c}\left(\frac{c^2}{\mu c^2}\right)^2\frac{\hbar\nu}{\mu c^2},$$

where μ is rest mass of meson. From this we calculate the slope of the lead transition curve to be 0·0015 cm.$^{-1}$ hour^{-1}, while the observed slope is found to be 0·2 cm.$^{-1}$ hour^{-1}. Thus the observed effect is much larger than that predicted on the assumption of meson pairs.

Another difficulty arises from the fact that, as the records show, most of the showers contain many more than two particles (see Table 2).

TABLE 2.

Number of rays	0	1	2	3	4	5	6	7	8	Total
Observed frequency	854	911	184	139	130	108	80	85	49	2540

Thus in order to maintain the assumption of meson creation by photons, one has to assume that the process in question is a multiple one, that is, one photon giving rise to several mesons simultaneously; alternatively, one can assume that the photons arrive frequently in large groups creating several independent meson pairs simultaneously.

Whatever is the actual process for the production of these penetrating showers, it is probable that they are produced by the soft component of cosmic rays, because (a) saturation is reached at about $T = 5$ cm. lead, and (b) the cross-section of their production varies as Z^2. If the penetrating showers do consist of mesons, then the result that the cross-section for their formation varies as Z^2 is consistent with some other evidence. An estimation of the rate of mesons produced in the atmosphere by the process responsible for the penetrating showers gives a reasonable rate of meson production on the assumption that the cross-section varies as Z^2; but on the assumption that the cross-section varies as Z the rate obtained is too high.

Pseudo-dominance in Polygenic Characters

F. W. Dry, P. R. McMahon and J. A. Sutherland in a recent communication[1] describe the inheritance of so-called halo-hairs (*N*-type) in lambs, which they found to have a multifactorial basis. *N*-type is, according to the authors, conditioned by a single factor dominant over the not-*N*-type (linked with the sex-influenced factor for horns, with crossing-over occurring about once in ten or twelve times).

But the authors found themselves a "little surprised" by one aspect of the situation, namely, that sometimes not-*N*-types (from *N*-type stock) produce *N*-type offspring. The authors suggest two explanations: two linked complementary factors for *N*-type, or dominigene hypothesis.

The observed facts require, I think, another interpretation. The reciprocal appearance of *N*-type in alternative generations is due to its polygenic basis, in which case an assumption of dominance, of dominance modifiers (dominigene) or of linkage is superfluous. The change in the usual dominance of *N*-type, or rather the appearance and disappearance of halo-hairs in succeeding generations, is a result of different assortment of modifiers, some of which (*I*) increase the number of halo-hairs, other of which (*D*) diminish it and cancel their appearance. If, for example, a lamb should inherit two modifiers *I*, each of which produces 100 halo-hairs per unit area, and four modifiers *D*, of which every one decreases the number of halo-hairs by 100, then this lamb would be not-*N*. These not-*N* animals mated together may produce lambs with halo-hairs (*N*-type) if they inherit more *I* genes than *D* genes. In the breeding experiment cited by Dry *et al.*, a not-*N* ram, son of an *N*-type son of the original *N* ram, was mated with not-*N* ewes (with no or few halo-hairs on the back), daughters of the original ram or of one or other of his *N*-type sons. The results were: 2 typical *N*-type and 9 not-*N* with halo-hairs absent or of low abundance on the back. These pseudo-dominant *N*-types appeared here from pseudo-recessive not-*N* parents, because these parents were polygenic and heterozygous for halo-hairs. The number of factors in the halo-hair character is probably a large one, and therefore the homozygous *N*-type, or homozygous not-*N* practically never occur. Consequently different recombinations are possible, producing the same visible type, *N*, and these pseudo-dominant *N*-types mated together give not-*N*; conversely the pseudo-recessive not-*N* (being polygenic and heterozygous) may produce *N*-type.

We cannot expect a constant ratio in F_2, but various ratios (sometimes accidentally a ratio 3 : 1), because the genotype of halo-hairs consists of many modifiers, and almost every polygenic *N*-type, or not-*N* depends upon a different assortment of genes.

For the same reason we can scarcely expect a ratio 1 : 1 in 'back-crosses', except by accident. This assumption is supported by results from 'back-crosses' which the authors obtained.

They say: "in back-crosses of heterozygous *N*-type (so regarded from their parentage) to not-*N*, some ratios are almost exactly 1 : 1, but in the offspring of some tested rams there is a deficiency of *N*-type, that is, an excess of lambs definitely not-*N*. Whether this deficiency of *N*-type is significant, and how it is to be interpreted if it is real, are matters calling for further experiment".

This "deficiency" is, we think, due to the fact that not only was the *N*-type heterozygous in these pseudo-back-crosses, but also the not-*N* was probably also a polygenic, heterozygous type, instead of a homozygous recessive. It was not a back-cross at all, but a mating of two heterozygous, polygenic types, which has given therefore different assortments of modifiers, and not a simple 1 : 1 ratio. This "deficiency" can be accounted for by the great excess of *D* modifiers in not-*N*.

The "dominance" of *N*-type seems to be an illusory one, and is not dependent on the dominance of the special gene for *N*-type. The *N*-type ram crossed with not-*N* ewes will sire *N*-type offspring, not because his halo-hair factor is dominant to not-*N*, but because the genotype of this ram includes a great number of modifiers *I*. For example, a (20 *I*, 2 *D*) ram mated to ewes of not-*N* (10 *I*, 12 *D*), having only a small excess of *D* modifiers, will give mostly *N*-type. Here we have a case of pseudo-dominance due to parents, with heterozygous polygenic character, transferring a great number of *I* modifiers to the following 'F_1' generation.

The appearance of not-*N* out of *N*-types by not-*N* is dependent on the presence of *D* modifiers in the *N*-type. These views are supported by the following statement made by Dry: "This *N* factor (or possibly *N* complex) sometimes comes to incomplete expression, so that the lambs fall a little short of the abundance of halo-hairs regarded as properly gross".

From the above we can see that the results obtained in F_1, or from 'back-crosses', are not always proof for dominance, that is, in cases where the character analysed is a quantitative one.

There are known in animals some other cases in which both parents of type *A* produce offspring of type *B*, and parents of type *B* produce *A* offspring. The inheritance of these cases (if polygenic) could be interpreted similarly as *reciprocal type of inheritance*. In polygenic characters we deal almost always with heterozygous material and consequently we can scarcely expect simple Mendelian ratios in F_2 or in back-crosses. The appearance or disappearance of a character in succeeding generations will depend on the numerical proportion of quantitative factors or modifiers. The excess of some will cause a given character to show (type *A*), and on the contrary the excess of the others will produce the opposite type *B*.

This reciprocal appearance of type A or type B will continue without special ratios in successive generations. It can be influenced by natural or artificial selection. After many generations of selection in one direction, there is produced an assortment of modifiers of the same type, and the observed character becomes pseudo-dominant.

Immunity from Cellular Changes in the Blood

CUMULATIVE evidence from a series of investigations on *Past. pestis*[1,2,3], specially in relation to active, passive and natural immunity and bactericidal tests *in vitro*, and *in vivo*, strongly suggested that the humoral factors could only be partly responsible for host resistance against a highly invasive organism like the plague bacillus.

During the course of studies on the cellular reactivity to plague infection it was observed that certain types of changes took place in the white cells of blood which, when studied by the supravital technique as described by Sabin and her collaborators[4,5,6], were found to be indicative of (*a*) active immunity, (*b*) passive immunity, and (*c*) susceptibility on the part of the experimental animal.

Bombay rats were employed for the study of active immunity since they are partially immune to plague infection, and a certain percentage of them always survived the test infective dose. Haffkine Institute inbred white mice, which have been shown to be most susceptible to plague[7], were used as controls as well as for passive protection tests. It was possible to study the cellular changes for a number of days in the same animal by bleeding it from the tail every morning and afternoon.

Both active and passive immunity were associated with the presence in the blood stream of those cells which have been variously described as clasmatocytes[8], histiocytes[9], and as wandering endothelial phagocytes[5].

(1) In active immunity there was a constant 'shower' of clasmatocytes which, along with an increase in the total number of leucocytes and abnormal functional activity on their part, indicated that the animal was going to survive. On the other hand, where, in a partially immune animal, the plague infection was going to prove fatal, the percentage of clasmatocytes was low and they were present for the first 48–72 hours only; the functional activity of both the monocytes and the granulocytes was below normal and the neutrophils gradually lost their motility and became rounded. Towards the end, the white blood cells presented a typical moth-eaten 'ground glass' appearance without vacuoles or granules. This picture always connoted a very grave prognosis and invariably ended fatally.

(2) In a susceptible animal, like the white mouse, no clasmatocytes were seen at any stage of infection. From the cellular point of view the animal took a downhill course almost from the very start. All the signs associated with grave prognosis developed by about the fourth day, and in spite of a total white cell count of 40–50,000 per c.mm., and a monocytic percentage as high as 25, the animal succumbed to infection on the fifth to seventh day.

(3) In passive immunity the presence of clasmatocytes was directly related to the envelope antibody—the protective component of an anti-plague serum[10]. There was, however, a threshold value below which the clasmatocytic cellular reaction was not observed. Above the threshold value the percentage of clasmatocytes and the duration of their presence in the blood stream depended on the amount of the envelope antibody administered.

The somatic component of an anti-plague serum, which in animal experiments was devoid of any protective value[3], was never found to be associated with the appearance of clasmatocytes in the blood stream.

The details of this investigation are being communicated elsewhere.

Pigments of *Iris pseudacorus*

A NUMBER of blue and purple varieties of the Iris family have been included in their "Survey of Anthocyanins" by G. M. and R. Robinson, who have specified the particular anthocyanidin present in each case. They have found, for example, that *Iris miranda*[1] contains a complex delphinidin diglycoside and that a malvidin 3 : 5 dimonoside mixed with what is probably a petunidin derivative is present in *Iris Kæmpferii*[2].

On the other hand, *Iris pseudacorus*, commonly known as the water-flag, owes its colour to the presence of carotinoids, a fact which was first established by van Wisselingh[3] from a cursory examination of the flowers by means of colour reactions.

We are at present engaged on a detailed investigation of the nature of the carotinoids present in *Iris pseudacorus*. We have succeeded in resolving the very complex mixture of pigments present into five different fractions. β-Carotene is present, and from the mixture of other pigments, which are xanthophylls, violaxanthin and lutein have been isolated and characterized. Whilst these constitute the major portion of the xanthophyll fraction, spectroscopic evidence disclosed the presence in very small amounts of what is probably zeaxanthin. In addition, a dark red wax-like substance, with absorption bands in carbon disulphide at 496, 465 and 436 μμ, was isolated. Kuhn and Winterstein[4] in their examination of the carotinoids of *Viola tricolor* obtained an unidentified coloured waxy product which had the same absorption maxima. The above xanthophylls are present in the petals in the ester form.

We hope to publish shortly a detailed account of this investigation elsewhere.

Influence of Purines, Creatinine and Creatine on the Oxidation of Vitamin C

IN a recent communication[1] evidence was presented to show the co-existence of oxidizing and protective mechanisms for vitamin C in plant tissues. While investigating the effect of various biologically important substances of very diverse nature, on the oxidation of vitamin C in presence and absence of $Cu^{\cdot\cdot}$, we have made some observations regarding the influence of purine derivatives, creatinine and creatine on the oxidation, which offers useful information regarding the nature of the protective mechanism existing in plant and animal tissues.

The oxidation of vitamin C was studied at *p*H 7·2 in presence of $Cu^{\cdot\cdot}$ in the Warburg manometers at 30°. The oxygen uptake was measured in the presence and absence of the substances under investigation, and the results are presented in the following table.

Ascorbic acid, 2 mgm.; $Cu^{\cdot\cdot}$, 0.71 μgm.; total volume 3 c.c. Air, 30°.

	Substance	Concentration *M*	μO_2 uptake	
			Time in minutes	
			15	30
Vitamin C + $Cu^{\cdot\cdot}$ +	None	—	66	130
,, ,, +	xanthine	0·00017	0	0
,, ,, +	uric acid	0·00015	0	0
,, ,, +	theophylline	0·00014	13	17
,, ,, +	theobromine	0·0007	65	120
,, ,, +	caffeine	0·00064	62	121
,, ,, +	creatinine	0·0011	5	10
,, ,, +	creatine	0·00095	62	130

The results show that the oxidation of vitamin C by $Cu^{\cdot\cdot}$ is completely inhibited by the purines—xanthine, uric acid and theophylline, in a final concentration of 0·00014–0·00017 *M*., while caffeine and theobromine even at higher concentrations have no influence on the oxidation. The imino group appears to exert influence on the inhibiting action of the purines, as only those of which the imino group is free (for example, xanthine, uric acid and theophylline) inhibit the oxidation, while those whose imino groups are methylated show no inhibitory effect (for example, caffeine). Further, the presence of methyl group in position 7 completely prevents the inhibiting action of the purines, although the other imino group is free (for example, theobromine). Thus the imino group in position 7 of the purine derivatives appears to exert a decisive influence on the oxidation of the vitamin.

An interesting difference between creatinine and creatine, the two important constituents of the muscle, is revealed by their influence on vitamin C oxidation. Although creatine has no influence, creatinine exerts powerful protection against the oxidation of the vitamin. Similar results were obtained when the oxidation of the vitamin was followed by titration with the indophenol dye.

In addition to glutathione and other thiol compounds which are known to exert similar protective action against the oxidation of vitamin C, the presence of purines and creatinine in the body may insure the existence of reduced vitamin C or prevent the oxidation of the vitamin by $Cu^{\cdot\cdot}$.

Further work on the mechanism of inhibition of the oxidation by the purine derivatives is in progress. Full details of the work will be published elsewhere.

Hydration of Carbon Dioxide and the Stability of Hypochlorite Aerosols

Powell[1] and Baker and Finn[2] have considered the effect of the slow hydrolysis of carbon dioxide on the stability of hypochlorite aerosols. The work of McBain[3] is quoted when in fact much subsequent work of greater accuracy has appeared; a summary of this work has recently been published[4]. In a series of experiments involving the accurate use of a difficult technique, Faurholt[5] measured the actual magnitudes of the rate constants for the reactions of carbon dioxide with water and hydroxide ion. The reaction with hydroxide ion is much the more rapid. The velocity of hydration in a given aqueous solution is thus a function of the *p*H, and can be calculated by summing the contributions to the rate by water molecules and hydroxide ions. In addition, the reaction is catalysed by bases and will be accelerated by anions of weak acids[6].

From these data the velocity of "changes occurring between the collision of carbon dioxide molecules in the air with droplets of the aerosol and the appearance of the corresponding hydrogen ion" can be easily estimated. It is noted[2] that the aerosols are decreasingly effective in acid, neutral, and alkaline solution. In alkaline solution carbonic acid would be produced from carbon dioxide more quickly than in acid or neutral solution; liberation of HOCl would occur more rapidly and loss of HOCl by evaporation would be more serious.

RESEARCH ITEMS

Fiction and Fact in Cultural Diffusion

WHEN, some years ago, battle was joined over the question of the diffusion of culture, it was categorically affirmed by members of the diffusionist school in anthropology that no element of culture, such as, for example, the wheel, was ever invented twice, but wherever it occurred it was a product of diffusion from a single centre of origin. Notwithstanding the obvious exaggeration of the statement in this extreme form, instances to the contrary susceptible of absolute demonstrable proof have not been found to be common. This has been especially true in one province, namely, the folk-tale. Here the argument for independent invention has to contend with a weight of evidence in the widespread occurrence of identities in character of motif and details of incident which, occurring time after time in a constant sequence, seem to preclude the probability of anything but a common origin. A familiar example is a folk-tale which occurs in a large number of variants distributed from India to Wales. Its motif is the faithful dog or other animal which is slain by its master on the evidence of bloodstains under the misapprehension that it has killed the child which it was its duty to protect. It occurs in the *Pañcatantra* as the story of the Brahman and the mongoose, and is widely current in India. In 1937 it was recorded among the Kotas of the Nilgiri Hills by Dr. D. G. Mandelbaum in the course of ethnological field-work, and has been studied for its bearing upon the diffusion problem by M. B. Emeneau with his collaboration (*Proc. Amer. Phil. Soc.*, **83**; 1940). The story as told among the Kotas deals not with ancient times, as is usual in their folk-tales, but professes to describe an event which actually took place "about eighteen years ago", the actors in the drama being named, and three of them, including the woman who killed the mongoose, and her son, the infant whom the mongoose saved, being still alive. Investigation in the tribe, and interviews with the persons involved, established the conviction that the event really happened and the story is not here an instance of a borrowed motif. It is suggested by the investigator that, failing acceptance of this conclusion, two alternatives are open—either that the record of an actual event was remade in the classical form, of which, however, the persons concerned and narrators deny any knowledge, or that subconscious knowledge of the classical story forced the woman to act as she did. This latter explanation would, the author points out, involve a peculiarly subtle form of diffusion.

Flint Flakes of the Crag Sea Floor

TRAPS and difficulties of interpretation in geology and prehistory are reviewed by S. Hazzledine Warren in his recent presidential address to the Essex Field Club (*Essex Naturalist*, **27**; 1940). Among these he discusses the Crag sea floor and its flaked flints—"the most important and the most controversial problem of prehistory". The discovery of the remains of the lower jaw of *Elephas meridionalis* at Runton a few years ago suggests by its associations—it lay in the middle of the sands of the Weybourne Crag under the rolled pebble bed at the base of the forest bed with fossil marine shells over, around and under it—that in the presence of a scouring current where sedimentation was arrested, such bones, when the carcass had drifted out to sea, would become broken up and accumulate as a rolled bone bed on the sea floor. Further, phosphatization is a sub-marine product, while the suggestion is in harmony with the rise in the Crag sea floor which brings the Crag sea level to above 300 ft. O.D. The associations of the Suffolk bone bed fall naturally into this epoch of submergence. At all the varying depths of the Crag Sea there is no visible break in marine continuity from the bone bed and stone bed to the overlying sediments. The most remarkable phenomenon of this ancient sea floor is the vast quantity of flaking that is distributed over it. Is the origin of this flaking Eolithic or natural? It has been argued (Prehist. Congress "Handbook"; 1932) that the Crag implements are contemporary with the basement bone bed and are not 'derived'. Drifting, however, must not be excluded nor can the inference that the bone bed was occupied by Tertiary man be accepted, unless he was of the mermaid race. In regard to the artificial origin of certain crude flakes, doubt arises from the observation of the effect of the passage of cart-wheels over flint on a new road. Exact reproduction of the forms claimed as eoliths are produced thereby. Further, eoliths are associated in geological deposits with striations that indicate that very movement under pressure that is required to produce flaking. During the last few years a swing of the pendulum has set in, and the realities of flaking by pressure are beginning to be better appreciated. The ultimate test lies in first-hand observation of the concrete material.

Isotope Exchange in Organic Compounds

Deuterium has been used as an indicator in the study of three-carbon tautomeric systems in which one isomeride is produced in large predominance. A study of an equilibrium state which is more balanced is provided by the system composed of Δ-pentenoic acid $CH_3.CH_2{\cdot}CH{:}CH.CO_2H$, Δ^{β}-pentenoic acid. $CH_3.CH{:}CH.CH_2CO_2H$, and β-hydroxyvaleric acid $CH_3.CH_2CH(OH).CH_2.CO_2H$ by D. J. G. Ives and R. H. Kerlogue (*J. Chem. Soc.*, 1362; 1940), which are involved in a 'triangular' system, each member being in direct equilibrium with the other two in an alkali-catalysed isomerization in water. This isomerization proceeds mostly by direct prototropic change but to a less extent by addition and subtraction of water, with the formation of the β-hydroxyacid as an intermediate. The deuterium exchange reaction was studied in a solvent containing deuterium oxide, and the results, although not investigated in detail, are in general conformity with the above reaction mechanism and indicate that a bimolecular mechanism is concerned in the prototropic isomerization.

A Theory of the Structure and Formation of Antibodies

A PAPER by L. Pauling (*J. Amer. Chem. Soc.*, **62**, 2643; 1940) develops a theory of the structure and process of formation of antibodies and the nature of serological reactions which takes account of the present knowledge of the structure and properties of simple molecules as well as most of the direct empirical information about antibodies. An attempt is made to develop the simplest structure for a molecule with the properties observed for antibodies and the simplest reasonable process for its formation. It is assumed that antibodies differ from normal serum globulin only in the way in which the two end parts of the polypeptide chain are coiled. These parts have many possible configurations and under the influence of an antigen molecule assume configurations complementary to surface regions of the antigen, thus forming two active ends. After the freeing of one end and the liberation of the central part of the chain, this part of the chain folds up to form the central part of the antibody molecule, with two oppositely directed ends able to attach themselves to two antigen molecules. These processes are made clear in the paper by several diagrams. It is shown in detail that most of the reported experimental results are compatible with the theory.

Properties of Liquids in Small Capillaries

SOME experiments by J. L. Shereshefsky (*J. Amer. Chem. Soc.*, **50**, 2715 ; 1928) showed that the observed lowering of vapour pressure of a liquid in capillaries of 2 to 6 microns in radius was considerably larger than that calculated by Kelvin's equation. This was attributed to an increase in surface tension in the small capillaries. In quartz tubes of radius 5 μ or greater, normal values were found with water, but abnormal values in tubes of 2·07 μ in radius. L. H. Cohan and G. E. Meyer (*J. Amer. Chem. Soc.*, **62**, 2715 ; 1940) have now made further experiments to find if the surface tension changes in small capillaries. Water and toluene were measured in pyrex glass capillaries of radii as small as 2 μ. The rises were large, in some cases more than 250 cm. The results indicated that the surface tensions and densities of the two liquids do not vary from their normal values within the limit of accuracy of the experiments, ± 5 per cent. The increase in surface tension thus cannot be accepted as an explanation of the abnormal vapour pressure lowerings found by Shereshefsky.

Quenching of the Resonance Radiation of Sodium

R. G. W. Norrish and W. MacF. Smith have reported the results of an experimental study designed to elucidate the behaviour of different molecules in quenching the resonance radiation of sodium (*Proc. Roy. Soc.*, A, **176**, 295 ; Nov. 1940). By using different homologous series, an attempt has been made to assess the specific qualities of molecular structure which can give rise to quenching. Quantitative indications were got from the strongly quenching gases, the saturated hydrocarbons and the inert gases, but only semi-quantitative indications from the weakly quenching gases, the unsaturated hydrocarbons and the amines. The difference in behaviour of the two groups of gases is too pronounced to be explained in terms of the discrepancy between the amount of energy the sodium atom gives up and the quenching molecule can receive. Unsaturation in the molecule seems to be the deciding factor. Within any one series the number of atoms in the molecule apart from the unsaturated centre appears to have little influence on the quenching ability, which may be regarded as proceeding from a centre of unsaturation. From a qualitative discussion of the results in the light of the Stearn and Eyring theory of non-adiabatic reactions, it is concluded that, in the terminology of the theory of the intermediate complex, the presence of unsaturation manifests itself in a relatively large transmission coefficient.

Periodicity in the Corona

K. G. MELDAHL has published a small work of 14 pages entitled "Tidal Forces in the Sun's Corona Due to Planets Compared with Wolf's Sunspot Curves" (Copenhagen : Berlingske Forlag) which is a continuation of his general investigation of the tidal forces in the corona (see NATURE, **144**, 726 ; Oct. 28, 1939). The author starts with a disturbance at 15° latitude as the basis, the daily rotation at this position being 14·48°, and deals with the relative and absolute tidal force periods, and finally with the inverse of their products : this is the velocity of rotation which is utilized for combining the periods and attaining the final results. These periods, combined in various ways, denote the time elapsed between repetitions of the mutual positions of bodies without regard to orientation in space. Looking for the possible results of combining numerical data, four solutions satisfy the condition that the result shall be negative, and of these it is found that a period of 11·279 years is derived from V+E+J−(M+S), these letters referring in order to Venus, Earth, Jupiter, Mercury, and Saturn. As explained in the previous review, Mars is neglected, as its tidal force is only about 3 per cent that of the earth. The half-periods of the planets were naturally used, in accordance with the tidal law, and the result is the Wolf's Zurich curves of sunspot periods, as shown in a figure. Meldahl considers that this affords additional proof of the correctness of the tidal force effect. The latitude 15° was selected because data for this region were available, but if latitude 13° is chosen a period of 11·125 years would result. It is claimed that a 9·548 years period obtained from V+E+S−(M+J) furnishes another proof of the tidal forces by apparently causing a beat in the curve in 1837 and a minimum region about 62 years later.

Star-Streaming and Spectral Type

W. M. Smart and T. R. Tannahill made an analysis (*Mon. Not. Roy. Astro. Soc.*, **100**, 1 ; November 1939), on the two-streams hypothesis, of the proper motions of stars of all spectral types in the Cape Astrographic Zone, the limit of magnitude being 9·0 on the C.P.D. scale. They now give a similar analysis for the spectral subdivisions *A*5–*F*5, *F*8–*G*5, *K*0–*M*, and also for the 11,448 stars in the spectral range *A*5–*M* (*Mon. Not. Roy. Astro. Soc.*, **100**, 8–9 ; June 1940). The results for the drift constants, the vertex of the star-streaming and the solar motion are given in tables for the various spectral groups, and it is interesting to notice that the stars in each spectral group are divided fairly equally between Drift i and Drift ii. In spectral groups *F*8–*G*5, the ratio of the number of stars in the two drifts is 1·038, and the close equality prevails also in the numbers (Table 3) dealing with the vertex of star-streaming and solar motion. This table shows that the longitude of the vertex is, on the average, about 15° higher than that of the galactic centre. The ellipsoidal constants have been derived by the method previously described by Smart, and are in good agreement with the values derived by Jackson from the same data but by a different method. The ratio of the axes of the velocity ellipsoid for the *A*5–*M* stars is 0·64, and this agrees well with Jackson's value, 0·60.

UTILIZATION OF ELECTRICITY IN AGRICULTURE AND HORTICULTURE

IN the report referred to below*, which was prepared originally for the guidance of the Electrical Research Association, Mr. C. A. Cameron Brown gives a very complete review of the experimental and research side of rural electrification. It is estimated that out of about a quarter of a million farms in Great Britain which are already, or are likely soon to be, within reasonable reach of an electric supply, only about one in eight has yet been connected. The main difficulty in the way of further development is the relatively high cost of providing a supply to the average farm. Most electrical development is based on the expectation that a new customer will bring in an annual revenue equal to about 20 per cent of the capital cost of connecting him to the system. Under present conditions, however, the average annual revenue from a newly-connected farm is unlikely to exceed £25; while the cost of connexion will almost certainly be considerably more than five times this amount. There are two possible lines along which a solution of this difficulty might be sought: to lower costs of connexion by simplification, standardization or other means; or to increase potential revenue by encouraging the wider application of electrical power on the farm; and it is to consideration of the second of these that the report is mainly directed.

Of the various fields of activity in which farmers use power, tillage is by far the largest and most important; but, from the point of view of electrical development, is one of the least hopeful. Battery-driven tractors are out of the question, while electrically operated winding sets, working on the same principle as steam ploughing engines, are too restricted in operation for the present-day farmer. The only real possibility lies in the electrically driven tractor fed from a stationary supply point, through a flexible cable which is paid out and picked up automatically as the machine manœuvres. The main technical problem is the design of a cable-winding mechanism which will give the tractor sufficient flexibility of movement; and it seems unlikely that electrically operated outfits will ever be able to undertake much field work beyond ploughing and the heavier cultivations. Their development would therefore seem to be quite out of tune with the present overwhelming tendency towards all-purpose tractors which can also be used for the after-cultivations of growing crops, and in haymaking, harvesting, transport and so on. Some practical progress in electrical tillage has, however, been made in New Zealand.

In the barnyard, where power may be needed for water supply, grinding and a whole range of food preparing operations, as well as for such subsidiary work as wood-sawing, the position is much more hopeful. In nearly all such operations, electrical power has the advantage of greater convenience; and although few directly comparable costs are available, there is good reason to believe that electric motors will give lower overall running costs than stationary internal combustion engines, provided that electrical power is available at rather less than 2*d*. per kilowatt hour. There is, however, room for developmental research: both into the kind of layout which will derive the greatest benefit from electrical working, and into the load factor of barn machinery. At present the typical barnyard engine is a fairly large one of, say, 10–15 h.p., which is regularly called upon to develop full power but which nevertheless will probably not do more than 500 hours of work in a year. As the report points out, running conditions as irregular as these are fundamentally wrong whatever the form of power used, and would be quite unacceptable to the supply engineer who might have to deal with some hundreds of similar cases in his distribution area. The remedy is, of course, the use of lower powered units which run for longer periods, but these will lead to uneconomical labour charges if they are not made practically automatic in operation, while to make them so will involve a considerable measure of barnyard reorganization. The Association's research programme includes some experimental work on these lines, and in the particular case of the grinding mill—the worst offender from the power factor point of view—useful progress has already been made.

In some of the more specialized branches of agriculture, electricity has more to offer than the mere replacement of one form of power by another. In dairying it has overwhelming advantages on grounds of cleanliness alone; while in poultry husbandry it has already been largely responsible for a great increase in chick production. At one time electrical incubation and rearing were regarded as being suitable only for raising 'soft' chicks for the table. Now, however, it is being realized that the same methods are even more suitable for the rearing of hardy stock. It has been found in practice that the dangers of loss from temporary failure of supply are not so serious as was once thought possible, and with the development in the future of storage brooder heating units these dangers will be reduced still further.

In horticulture, less progress has been made because the industry depends mainly on sources of low-grade heat with which, at any rate in the larger-scale commercial applications, it is difficult for electricity to compete economically. In small-scale work and in the amateur greenhouse, on the other hand, sheer economy of working is not always the ruling consideration. In horticulture generally, however, there is plenty of scope for research and experiment: on the use of heating cables for hotbeds, on soil sterilization, and on the use of light for irradiating growing plants.

The last of these is only one of a number of very interesting future possibilities which are dealt with separately in the concluding section of the report. Among others that may be mentioned are crop drying, grain sprouting, electro-culture and ultra-violet irradiation. At the moment their interest may be academic rather than practical; yet they may very well change the face of agriculture in the not too distant future.

---

* A Critical Study of the Application of Electricity to Agriculture and Horticulture. By C. A. Cameron Brown. (Technical Report Ref. W/T2.) Pp. 84. (London: British Electrical and Allied Industries Research Association, 1940.) 2*s*.

The report as a whole deals with the situation as it existed at the outbreak of war; and it cannot be expected that much further progress will be made within the next year or two. At the same time, as is pointed out in an introductory footnote, the War has brought many of the potential advantages of electricity into even sharper relief. From a shortage of cod liver oil comes a new interest in ultra-violet irradiation; the more frequent use of female labour makes ease of control an important consideration; scarcity of imported feeding stuffs encourages a return to the earlier practice of grinding and preparing foodstuffs on the farm; and so on. But, in his final summary, the author of the report takes the longer view and looks forward to the time, twenty-five or forty years hence, when on all but a small proportion of unreachable farms electricity is used as a matter of course, for all stationary power and for all heating operations. This state of affairs is very likely to come about—not, perhaps, as the direct result of technical or agricultural research, but as a matter of sociological progress. The future of agriculture in Great Britain is bound to depend a great deal on giving the rural dweller his due share of urban amenities, and in America it is recognized already that the seller of electric kettles, cookers and washing machines plays a great part in the spread of farm electrification.

FORESTRY IN AFRICA

IT is interesting to note in recent annual forestry reports how what may be termed a correct and long-sighted forest policy is gradually becoming recognized by the civil administration as a matter which can no longer be left to chance. This has recently been exemplified in NATURE. In the Gold Coast annual report (1938–39, Govt. Printer, Accra, 1939) the Conservator, in discussing the history of the forests, says that though some thirty-one years ago the indirect value of the maintenance of a proportion of tropical lands under forest was clearly stressed, yet the progress of reserving forests for the use of future generations, the maintenance of soil fertility, and so forth, has not proved an easy task. Forests, of necessity, occupy land, he says; and difficulties are increased when all the land, although surplus to immediate wants, is owned by a community with an unawakened national sense; to the individuals the cash resulting from an immediate sale is much to be preferred to the somewhat abstruse prospects from reservation in favour of future generations or a possible improvement in their water supplies. The failure to press for a more rapid selection of forests for reserves when surplus land was plentiful has resulted in an increasing opposition which education and propaganda are only gradually lessening; while the remaining forests of the Colony can no longer be regarded as excessive if the happiness and health of the community are to be assured.

In the Nigerian forestry report for 1939 (Govt. Printer, Lagos, 1940) the Conservator re-defines the aims of forestry in that part of West Africa on the well-known lines which have been so often in the past disregarded by the Governments. He sounds a wise note, too often neglected, that the productive motive, though secondary (it has usually been placed first), is an important one. "If," he says, "forest, shelterbelts and shade trees have to be maintained for protection, it is clear that the fullest possible use should be made of them, and this can best be effected by fostering African industries using forest produce as raw material." These industries, as was foreseen several years ago by senior French district administrative officers in the Ivory Coast, will in the future be more important in the economy of the country than any export trade in timber overseas. It is a step in advance that the head of a West African Forest Department should at length express this important view. The Conservator remarks that the Department is becoming continually more involved, with other rural departments, in the study of the wider problems of land use and land planning. But here again new forest reservation, so urgently needed, proceeds slowly in the south owing to political and legal difficulties and problems of land tenure; and this in spite of the fact that all the forms of deterioration—of soil, climate and water supply—are in active progress in various parts of the southern provinces. There can be little hope of more than local remedy until the chaotic situation as regards land tenure is resolutely tackled.

The annual forestry report for Kenya for 1939 (Govt. Printer, Nairobi, 1940) strikes rather a different note. The outbreak of war has caused some reduction of the staff (junior officers allowed to join or called up to join the Army, which has been the case in both Nigeria and the Gold Coast), but has considerably increased the demand for forest produce. This latter and the increased revenue thereby realized might have proved of some satisfaction to the Department—especially the revival in the old export trade of boritis (mangrove) poles—were it not for the former factor. The demand for produce from the forests was increased during the latter part of the year by War Department demands. At all sawmills trade was fairly brisk, and several millers increased their output considerably by improved organization and efficiency. Unfortunately the urgent military demand for building timber has meant that air-seasoning has not been possible prior to the delivery of the timber.

Regrettable as this may seem, equally unfortunate is the fact that most of the timber requisitioned by the military authorities in war-time is utilized for purposes often ephemeral and in any event has a comparatively short life. A far more important point is the factor that, with a reduced staff, who is to undertake the necessary supervision over the extra fellings which are to take place? The limit to further indiscriminate fellings and resultant ultimate disappearance of the African forests has been reached, or is perilously close. If war fellings are to take place unchecked in forests the volume content of which is but imperfectly known, neither administration nor the local forest department is fulfilling its true functions to the native communities.

THE BRITISH PHARMACOPŒIA IN WAR-TIME

THE text is available of a further addendum to the British Pharmacopœia. Published under the direction of the General Medical Council, it became effective on January 1. Of main interest is the inclusion of monographs on a number of synthetic substances, formerly of foreign manufacture, and first introduced to the medical profession under proprietary names, which are now produced in Great Britain, in some cases under licences granted by the Comptroller-General of Patents.

The probability that certain 'new remedies' of this type would be introduced into the British Pharmacopœia in due course has already been mentioned in NATURE (August 31, p. 309). In selecting eleven of the more important of these products for official recognition the authority has adopted new names for their pharmacopœial titles. The substances under their official designations are as follows, the names in brackets being those under which they were first known: bromethol (avertin), carbachol (doryl), hexobarbitone and soluble hexobarbitone (evipan sodium), iodoxyl (uroselectan-B), leptazol (cardiazol), mepacrine hydrochloride (atebrin), mepacrine methanesulphonate (atebrin musonate), nikethamide (coramine), phemitone (prominal), and stibophen (fouadin).

The purpose of laying down standards for these products is to ensure that important synthetic remedies previously obtained from abroad will continue to be available in medical practice; the substances can be so adequately tested for identity and purity by chemical means that no question of the equivalence of the British preparations can arise.

Other monographs which have been added are on aneurine hydrochloride, chlorocresol, and paste of tannic acid. The inclusion of aneurine hydrochloride is of general interest since it is the vitamin—B_1—which it is proposed to add to white bread to replace the loss resulting from milling. Aneurine, which is also known as thiamine, plays an important part in carbohydrate metabolism. Chlorocresol (*para*chloro-*meta*cresol) has been added because of its use as a bactericide in sterilizing solutions for injection and as a bacteriostatic preservative in certain solutions; it is one of the ingredients of the newly introduced paste of tannic acid.

Monographs which are amended are those on atropine sulphate, injection of bismuth salicylate, hard soap and soft soap. The only change in the case of atropine sulphate is in the official statement of the melting point; for lead plaster arachis oil may be used in place of olive oil, and the alterations in the monographs on the soaps are made with the object of enlarging the choice of vegetable oils and authorizing the use of soda instead of potash in the process of saponification.

The addendum also embodies monographs which had already been amended by notices in the *Gazette*, the items concerned being lead plaster, injection of mercury, injection of mercurous chloride, strong ointment of mercury and ipecacuanha. Amendments which have been made in the appendixes, which relate to tests, are naturally the result of the additions to the British Pharmacopœia and the alterations which have been effected by the new addendum.

FORTHCOMING EVENTS

Monday, January 13

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 3 p.m.—Prof. H. A. Harris: "Growth in General".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Prof. O. T. Jones, F.R.S., and Mr. W. V. Lewis: "Water Levels in the Thetford Meres".

Tuesday, January 14

ILLUMINATING ENGINEERING SOCIETY (at 32 Victoria Street, London, S.W.1), at 2.30 p.m.—Dr. W. D. Wright: "The Fundamental Principles of Vision in Very Weak Light".

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 3 p.m.—Prof. H. A. Harris: "The Anatomy and Physiology of Locomotion and Posture".

Wednesday, January 15

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Miss Caroline Haslett: "Women in Industry".

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 3 p.m.—Prof. H. A. Harris: "The Inherent Weaknesses of the Human Body with reference to Orthopædic Practice".

Thursday, January 16

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 2.15 p.m.—Prof. P. A. Buxton: "Some Recent Work on the Louse".

PHARMACEUTICAL SOCIETY (at 17 Bloomsbury Square, London, W.C.1), at 2.30 p.m.—Mr. Arthur Mortimer: "Drug Supplies in War Time".

Friday, January 17

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (in the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Mr. G. E. Manville: "Optical Instruments: particularly Large Astronomical Telescopes".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT ENGINEER FOR THE MALAYAN PUBLIC WORKS SERVICE—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9306).

HEAD OF DEPARTMENT OF TRAINING COLLEGE AND SCHOOL OF DOMESTIC SCIENCE of the Witwatersrand Technical College, Johannesburg—Frank Ross and Co., 9 Fenchurch Avenue, London, E.C.3.

UTILIZATION OF MAN POWER

THE new appeal for volunteers for training for war work and the emphasis placed on the need for the employment and training of women show that the magnitude of the man-power question is now at last being recognized. Mr. Bevin has indeed, during the time in which he has exercised his immense powers of control over labour and industry, been fully alive to the importance of the human factor. He cannot be accused of being unmindful of the findings of the Industrial Health Research Board, and the stress he has laid in various speeches on the provision of canteens, communal feeding, and the safeguarding of health have indicated his profound concern with the maintenance of morale and health. There is, indeed, no room whatever for doubts as to the Minister of Labour and National Service holding a long-term view of industrial efficiency, and as to his determination to allow no short-sighted views of output and hours of work to impair the physical, mental and moral capacities of the workers on whose endurance, skill and enthusiasm we depend for long-sustained production.

Such uneasiness as may exist in regard to the man-power position and its handling arises largely from the same type of considerations as have led to criticisms of the scope and functions of the new Ministry of Works and Buildings. It is a question of the co-ordination and direction of our war-effort to the maximum efficiency. It is to be hoped that the new executive committee of Cabinet Ministers announced on January 6 will secure a measure of the co-operation which is imperative.

Examples of this lack of co-ordination are easily found. The Limitation of Supplies Order is part of a consistent policy of the Board of Trade to cut down severely the volume of manufacture for the home market. The aim of this policy is not merely the restriction of spending by the general public, but also, and equally important, the reduction of effort in non-essential industries. Similarly, the change of export policy from one of indiscriminate encouragement of all exports to one of selective encouragement is bound to result in displacement of labour in the manufacturing industries, distribution and perhaps especially among the retail shopkeepers.

In theory, the labour thus displaced is available for, and should be taken up by, the munitions industries. In practice, despite the somewhat misleading figures issued by the Ministry of Labour, it is not being taken up, or at least absorbed, with the completeness and rapidity that are desirable. There is little evidence of effort specifically designed to assist the transition by training in advance.

The failure of the Board of Trade and Ministry of Labour to dovetail is the more serious in view of the strain which sustained air attack places on the civil population. Consideration of the welfare side of the transition of labour, educational work designed to prepare men and women for change, to free them from unnecessary hardship or anxiety, is just as important a factor in the smooth supply of the million more workers required by next August for the armaments plan of the Ministry of Labour as it is in the handling of the dilution problem and the training of fresh labour in the shops, both as regards employers and individual workers. The Government is perhaps awaiting the results of the survey on which Sir William Beveridge is engaged, before committing itself to a more definite policy. It is time more was heard about this survey.

The million workers required can only be obtained by ruthlessly squeezing labour out of the non-essential industries, and there is little evidence that the reduction of the personnel of the non-essential industries is being carried through in anything but the most haphazard way. The Government has been silent, too, about the pooling of enterprises, or about compensation for works closed down—factors which also affect morale. There is no indication of prompt and firm administrative action to prevent wastage among labour evacuated from the coasts, or among that, often highly skilled, temporarily displaced by air-raid attacks.

The simultaneous immensely larger demands of the fighting services for men, who will have to be provided from the same source and even from among present war workers, makes the ruthless elimination of waste of man-power of the utmost importance. Civil defence workers provide a further complication. The balance between the different branches of civil defence—fire services, first aid, rescue and demolition services—requires reconsideration in the light of experience of recent months. Moreover, the most effective use of the minimum number of full-time workers consistent with safety cannot be secured without efficient organization of the much larger body of part-time workers, whose morale and efficiency, it should be remembered, are determined both by that of the community in which they live and of the industry in which they are engaged. Much more might be done to ensure the rational use of such part-time services in ways which would foster their keenness and loyalty without putting intolerable strain on their health or devotion.

Such organization of civil defence services, including the provision of reasonable amenities during the additional strain which weather and darkness impose during the winter months, is an essential part of the efficient use of our man-power resources. The wise use of military resources in the more technical tasks of clearance and repair to reinforce labour already available is an example of the type of elasticity and co-ordination required.

As already suggested, much more might be done to minimize the stress and strain of the vast change-over required. Most important at the present moment, however, is the problem of the large-scale training of men and women whose normal jobs have come to an end. Moreover, something in the nature of a system of priorities may be demanded in regard to man-power as well as supplies.

What must be realized is that the new demands involve a profound disturbance, not merely of our standards of living, but also of our domestic life. The great army of women workers required for our munition factories will not be recruited without grave social problems being encountered, both within industry and without. The reactions on the supply of helpers for many of the voluntary services of all kinds may be seriously adverse.

The importance of the proper distribution of skilled labour is not yet sufficiently recognized. Until it is distributed among the thousands of firms in the manner best suited to the mass production of munitions, we shall not achieve our maximum production, nor indeed be able to utilize effectively in the less skilled jobs our full resources of man- or woman-power. Skilled labour of any kind must in fact be regarded as first the possession of the State, rather than of any individual firm.

Recognition of key workers, especially tool-room workers and machine-setters, as a sort of national pool must be followed by proposals to make such a declaration more effective in the day-to-day hiring and employment of such industrial craftsmen. Further, this is true also of the training of the rank and file of fresh workers to do the less skilled jobs. These men and women are being trained to enter industry at whatever point their services may be needed, and the particular employer of any trainee is no more than the agent of the Government, upon whose production programme the scale and incidence of these extra labour requirements directly depend.

Mr. Bevin's references to the importance of psychological factors as a justification for not resorting to compulsion may in theory be sound enough. But there must be no squeamishness in dealing with anything allied to obstructive tendencies. There are already indications of undue deference, if not subservience, to vested interests in various fields, including that of food policy and agriculture, which endanger the high mood in which the nation faced the perils of early summer.

The need for wise planning and central direction of our man-power policy is cardinal, but the central machinery and plan must function smoothly. Just as the National Register can only be used to complete or perfect the main process of transfer or adjustment initiated in other ways, so the increasing attention to the safety of workers in factories, the improvement of amenities, the provision of canteens, the placing of workers to eliminate unnecessary travelling, and the avoidance of excessive hours of work, are designed essentially to ensure that man-hours vital to output are not lost by allowing conditions to arise that impair health and efficiency.

As already emphasized, such factors have to be considered in relation to the conditions of the civil population as a whole. Billeting and dispersal plans prepared to facilitate uninterrupted industrial production cannot be considered apart from arrangements made in regard to the evacuation of school children or other special classes of the community. Education itself must be considered in reference to the *morale* of the adolescent population and the future supply of juvenile workers throughout the national life. Moreover, there is still evidence of failure to make full use of the available services of special types of worker; as, for example, of biologists, or of various classes of friendly aliens at present interned, though the recent orders for registration of the latter for employment is a step in the right direction.

The seriousness of the challenge which is now thrown down to us by night-bombing and by the attacks on our shipping must not be mistaken. No prejudices must stand in the way of the gigantic effort demanded of us. However severe those demands, or drastic the sacrifices they may involve of ways of living and freedom, it is certain that if they are presented with imagination and understanding, they will evoke as great a response as the disasters and perils through which we have already passed.

PHYSICS IN MODERN LIFE

Physical Science in Art and Industry
By Dr. E. G. Richardson. Pp. xi + 293 + 6 plates. (London: English Universities Press, Ltd., 1940.) 15*s*. net.

IN a specialist age such as the present, there must be a grievous loss of that legitimate pleasure which derives from the possession of knowledge over a wide field of human endeavour. Again, it is clear that much needless duplication of effort is continually going on, because people wholly absorbed in prosecuting one particular quest (probably with great zeal and application) are partly or wholly ignorant of what others are doing in another sphere, and whose methods might readily be adapted with very little trouble. There seems to be no ready-made cure for this state of affairs. Experience shows that even the most watertight and elaborate system of cross-references to cognate subjects fails to inspire us with a keen desire to look over the wall into our neighbour's garden.

Dr. Richardson, however, is a missionary. He has taken upon himself the task of discussing anything and everything—so far as the compass of his book permits—which physics can do in modern life. A random glance at the index produced such entries as 'cotton', 'decibels' and 'tilth'; from such an assortment, the scope of the volume can be envisaged. The author's style is easy, even perhaps colloquial here and there, and certainly the reader will have few dull moments, as he is swept along with an enthusiasm almost contagious.

The physics of locomotion occupy three chapters: these are followed by others dealing with communication, pottery, cooking, the farm, hydrology, mining, fine art and archæology, building materials, architecture, music, textiles and war. (It is a relief that the last-named is quite short, and that there is no inclination for its subject-matter to seep through into the rest of the book.)

Naturally, a work such as this offers unrivalled opportunities for any reviewer to dwell upon omissions, and some readers, too, will find their pet notions unrecorded; nevertheless, it is astonishing how complete and coherent the treatment is, and this without any obvious tendency to 'write round the references'.

To make a few specific comments: the section on aeroplanes contains an excellent description of the theory of similitude—and its relation to models—without the introduction of mathematical machinery. This is an example of the way in which Dr. Richardson will probably succeed in helping people to realize that there is such a subject, and that having done that, there is a fair chance that they may discipline themselves to appreciate its beauty when handled analytically.

The development of the locomotive is well brought out. A point which might have been worth making here is that the remarkable capacity for speed shown by engines of recent types (even with coupled wheels of relatively small diameter) is due almost entirely to radical improvements in 'front-end' design, and the study of the flowing properties of highly superheated steam. The speeds reached by the 'singles' of last century were not, generally speaking, very noteworthy (as the author truly points out), a fact mainly attributable to their unscientifically conceived ports and blast-pipes.

The wheel now turns full circle, and the reader may re-open these pages to find himself engrossed in the technics of art. It would have been kind if he had been directed towards that remarkable publication "Technical Studies in the Field of the Fine Arts" (Fogg Art Museum, Harvard University), which, for several years past, has been disseminating knowledge of just the sort which—in this particular domain—Dr. Richardson is so rightly anxious to increase, and for which he is striving to gain appreciation. In this connexion, Fink's ingenious researches into the cleaning of pottery by electro-endosmosis would have made a charming pendant to the chapter on ceramics.

Thus one can go on: it is an unending theme, as limitless as the powers of applied physics themselves. This volume should be widely read; schools would do well to add it to their libraries without question; for other folk it will be found to be considerably more than a 'scientific bed-book', although it might sometimes well serve that purpose. Here, in fact, is a cross-section of twentieth-century activity, seen in sharply defined relief against its historical background.

F. I. G. RAWLINS.

PERIODICITY IN MALIGNANT GROWTHS

The Periodicity and Cause of Cancer, Leukaemia and Allied Tumours

with Chapters on their Treatment. By Dr. J. H. Douglas Webster. Pp. xv+178. (London: Baillière, Tindall and Cox, 1940.) 12*s.* 6*d.*

DR. WEBSTER'S main thesis is that malignant tumours do not grow continuously but show alternating periods of activity and quiescence. This behaviour is attributed to the nature of the life-cycle of the virus responsible for the disease. The full period for one part of the cycle is thirty-three weeks, but the great majority of cases show half periods and multiple periods.

In spite of the elasticity that is apparently allowable, it is very doubtful if Webster has established his main point. Naturally, interest centres around the evidence of periodicity to be found in untreated cases. Unfortunately in such cases we usually have to rely upon the account given by the patient. Thus, if a patient first notices a lump in January and says that it remained stationary in size until the middle of July, when it suddenly began to grow rapidly, then the period January–July represents a full period of quiescence. Those of us who have actually measured tumours over considerable periods may perhaps be forgiven the belief that the apparent discontinuity in the behaviour of the tumour is very likely an expression of psychology rather than of tumour growth.

Bashford is quoted as having been the first to establish experimental evidence of periodicity in tumour growth. The rhythms observed by Bashford and his colleagues were expressed in terms of the percentage of successful inoculations. Unfortunately this evidence, even if it were germane, would have to be discounted, since modern genetic experiments have shown that these rhythms are artefacts. This statement cannot be fully discussed here; nobody has brought any serious criticism against the genetic evidence, although it must be admitted that several people choose to ignore it. In general it may be stated that experimental work lends no support to the idea that malignant growth is fundamentally rhythmic in character. It is possible that rats and mice do not live long enough for the rhythm to be shown, but this argument loses force when applied to the rabbit, an animal in which virus-induced tumours have been observed over considerable periods without elucidating any fundamental rhythmic pattern.

As further evidence in support of his main thesis, Webster quotes several instances in which the time of recurrence was successfully predicted in cases undergoing treatment. Here it is not necessary to make any assumption concerning the nature of malignant growth; all that need be assumed is that the growth-rates of tumours are fairly closely grouped about a mean value.

Whilst few would deny that malignant growths may sometimes show surprising periods of quiescence or sudden changes in growth-rate, evidence that alternating periods of growth and quiescence should be regarded as the normal sequence independent of any treatment is still lacking. It is, of course, possible that variations in a virus may be responsible for some of the more obscure points in the behaviour of malignant cells. Up to the present, evidence on this point comes entirely from the laboratory. The data supplied by the clinician cannot as yet be said to have added anything of value.

P. A. GORER.

COCONUT DISEASES

The Diseases of the Coconut Palm
By Prof. H. R. Briton-Jones. Revised by Prof. Ernest Entwistle Cheesman. Pp. xvi+176+37 plates. (London: Baillière, Tindall and Cox, 1940.) 10*s.* 6*d.*

TO those who worked in close contact with the late Prof. H. R. Briton-Jones, professor of mycology in the Imperial College of Tropical Agriculture, Trinidad, the keen interest which he invariably displayed in attempting to make scientific investigations of direct use to the planter, and his sympathy towards the practical and economic difficulties by which the tropical agriculturist is so frequently beset, are common knowledge. This attitude is implicit in the work now under review. Its object, clearly stated in the preface, is ". . . to give those growers who have not had the advantage of a scientific training, and those agricultural officers who, through pressure of work in other directions or lack of library facilities, are unable to keep up with modern scientific literature, an account of the diseases of the tall coconut palm in simple English, with, it is hoped, a sympathetic understanding of the practicable limits of labour intelligence and the monetary unit in crop production under tropical conditions". On this basis the book must be judged. It may be said at once that in respect of directness and simplicity of presentation and choice of illustration the author has succeeded in no small measure.

The approach is appropriate to the subject. The tall coconut palm, one of the major tropical crops, is widespread in its distribution. Its cultivation has been attempted over a wide range of conditions, often unfavourable, with concomitant disease incidence and financial loss. Not least, the size and nature of the plant render it one of the least suitable subjects for the study of physiological processes. Where these are related to pathological aspects the approach tends to be by inference and analogy rather than by direct experimental observation. The author of the present work has faced such difficulties courageously, and, at the risk of laying himself open to criticism, has not hesitated to speculate freely on occasions where precise information has been scanty. The same attitude applies to the criticisms which are here and there made of the findings of other investigators.

The opening chapter refers to the bud rot complex, the analysis submitted doing much to clear the way for a straightforward exposition of the diseases described in subsequent chapters. The term 'bud rot', in fact, with one exception (*Phytophthora palmivora*), "is merely descriptive of a concomitant symptom of different kinds of diseases fatal to the coconut palm". Thereafter bronze leaf wilt, Phytophthora bud rot, tapering stem wilt, red ring disease, false wilt and lightning strike, stem-bleeding disease, root and leaf diseases, gumming disease and dropping of nuts, are dealt with in considerable detail, symptoms, environmental conditions, and relevant cultural practices being clearly indicated.

The account of bronze leaf wilt, attributed to drought in conjunction with unfavourable soil factors, is typical of difficulties arising in the study of this crop. In some instances the line between health and disease is very narrow; some affected plants may recover whereas others, in what appears to be approximately the same pathological condition, may succumb rapidly. Close and continuous observation is necessary in order that the slightly different symptoms may be correctly assessed. In a malady where anatomical investigation yields almost no symptoms of definite diagnostic value, such behaviour as that cited indicates clearly the difficulties and pitfalls that await the pathologist. Again, roots, though frequently abnormal and in a decayed condition, so far have only yielded a Diplodia species, an organism regarded as being only of secondary importance. Nevertheless, bronze leaf wilt ranks very definitely as a destructive disease, and, as the author's photographs and text plainly show, is one that may take a heavy toll of plantations of all ages. The account of this disease also directs attention to the fate that inevitably overtakes a crop the cultivation of which has been attempted under unfavourable environmental conditions.

The discussion of the several major diseases is on the same broad basis as that indicated for bronze leaf wilt. Where the author does not agree with the findings of other workers he has not hesitated to say so. In several such instances it is only too evident that our information regarding the physiological processes and reactions of such an unwieldy object as the coconut is quite inadequate, and that theory rather than fact will to some extent tend to hold the field until this defect is made good.

Lastly, in recommending this very readable book to planter and pathologist, reference should be made to the careful revision carried out by Prof. E. E. Cheesman and to the useful additions of recent literature incorporated by him, which bring the book quite up to date.

C. W. WARDLAW.

ASPECTS OF THE THEORY OF STATISTICS

(1) A Detailed Proof of the Chi-Square Test of Goodness to Fit.

By E. Russell Greenhood, Jr. (The Harvard Phi Beta Kappa Prize Essay for 1939.) Pp. xiii + 61. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1940.) 8*s*. net.

(2) Statistical Calculation for Beginners

By E. G. Chambers. Pp. viii + 110. (Cambridge: At the University Press, 1940.) 7*s*. 6*d*. net.

(3) Elements of Statistical Reasoning

By Prof. Alan E. Treloar. Pp. xi + 261. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 19*s*. 6*d*. net.

(4) Mathematics of Statistics

By John F. Kenney. Part 1. Pp. x + 248. 12*s*. 6*d*. net. Part 2. Pp. ix + 202. 11*s*. net. (London: Chapman and Hall, Ltd., 1940.)

STATISTICS is fast taking the place of mathematics as the matrix of the sciences. The individual is giving place to the aggregate, the point of location to the interval of confidence and the categorical assertion to the statement in probability. But as yet the subject has not reached that distinctive stage of development which is signalled by the appearance of a comprehensive and rigorous theoretical treatise; and it never will reach the stage at which a comprehensive account can be given of its practical applications in any work smaller than an encyclopædia. The result of these conditions has been the appearance, over the last few years, of an extensive crop of text-books dealing with more or less specialized aspects of the subject. Here is a sample of the harvest of 1939–40, not, on the whole, a vintage year.

(1) Mr. Greenhood's essay is an illustration of the need for a treatise on theory. Like many other students, Mr. Greenhood was presented with the chi-squared goodness of fit test and asked to take it on trust. Unlike many other students, he refused to do so. There being no readily available account of the mathematical and distributional theory on which the test is based, Mr. Greenhood attempted to worry one out for himself from the admittedly difficult papers in scientific journals. His interest in the subject survived this experience (which, in his own idiom, is something to say) and he produced the proof set out in this essay. He claims no originality for his work; but his treatment has at least an unusual piquant imagery, as instanced by his comparison of the contour lines of a bivariate normal surface to a family of concentric lopsided doughnuts.

It is appropriate enough that a member of Phi Beta Kappa should expound the mysteries of Chi, and as usual when Greek joins Greek, there is a great display of vigour and pertinacity. But it is not really necessary to take 61 pages to demonstrate the validity of the chi-squared test, and at eight shillings the book is much over-priced.

(2) Mr. Chambers' little book is an unpretentious attempt to explain how to perform the arithmetic of the common statistical processes, with special regard to the needs of students of the psychological and biological sciences. One opens it with hopes that the author has found some new ways of lightening the burden of arithmetical drudgery which weighs so heavily on the statistician, but in this respect the book is somewhat disappointing. Mr. Chambers has nothing to add to what already appears in published text-books. That being so, it is not evident to me for what class of reader the book is designed. Those who have the theoretical knowledge to use these arithmetical processes will have already encountered them in acquiring it; and those who have not the knowledge would do well to leave them alone.

(3) Prof. Treloar is concerned mainly with the fundamental concepts of statistical theory, and has endeavoured to deal with them in a systematic way unencumbered so far as possible by mathematical and arithmetical complications. The result is a very lucid and balanced book which will be read with profit by anyone who wishes to familiarize himself with statistical reasoning without spending too much time on analytical and computational details. It is somewhat elementary in scope—there is little, for example, about inverse probability, likelihood, fiducial limits, confidence belts and so forth; but Prof. Treloar hints at the possibility of a second volume on these topics. This is one of those books which bear the marks of experience in teaching the subject, and should have a general appeal.

(4) Mr. Kenney's two volumes are not so much a book as a compilation, and not a very good compilation at that. His first volume deals with the standard subjects of descriptive theory, frequency distributions, location, moments, dispersion, curve fitting and correlation; his second with probability, bivariate frequency, partial correlation, sampling theory, chi squared and statis-

tical inference. There are a number of examples, the best of which are taken from other authors.

The two volumes differ very much in the standard of mathematical knowledge required by the reader. In vol. 1 "no mathematics beyond the ordinary Freshman course in college algebra is required", although "a certain degree of mathematical maturity and intelligence is presupposed". One result of this is that Mr. Kenney finds it necessary in the chapter on curve fitting to prove over several pages such theorems as "If $y = f(x)$ is linear the rate of change of y with respect to x is a constant"—and this despite the fact that topics such as integration and interpolation have already been introduced. One would have thought that the mathematically mature mind would have accepted this result without proof and left Mr. Kenney space to include some really important material such as the method of fitting polynomials of degree greater than two. Vol. 2 is a little more advanced, but even this is only intended "to prepare the student for the really mathematical part of the theory of statistics". One cannot help wondering why Mr. Kenney called this book "The Mathematics of Statistics", unless it was on the *lucus a non lucendo* principle.

It is evident that a work of some 450 octavo pages cannot cover the whole field of statistical theory and that some selection of topics has to be exercised; but Mr. Kenney's principles of selection are difficult to grasp. There is a chapter on moments, but no word of moment-generating functions or semi-invariants. There are some pages on confidence intervals, but nothing on likelihood. The chi-squared distribution is derived in detail from the multinomial, but the simpler and equally important result that the normal curve is the limit of the binomial is stated without proof. In reciting the tests of significance of the correlation coefficient Mr. Kenney omits to give a reference to R. A. Fisher's classical paper on the distribution of the coefficient in normal samples, or to Miss David's tables of its probability integral, though several less important contributions are mentioned. He says that the most important Pearson curves are Type III and Type VII (the normal curve), mentions the trivial Type X, and ignores the three main types of the Pearsonian system.

Mr. Kenney's book is a step in the right direction and there are some good chapters, for example, on small sample theory; but most of the topics on which he touches require a more thorough treatment if their statistical and mathematical implications are to be properly grasped.

M. G. Kendall.

CULT AND CRAFTS IN EARLY PALESTINE

Lachish II (Tell-Ed-Duweir):
The Fosse Temple. By Olga Tufnell, Charles H. Inge and Lankester Harding. (The Wellcome-Marston Archæological Research Expedition to the Near East, Publications, Vol. 2.) Published for the Trustees of the late Sir Henry Wellcome. Pp. 104 + 73 plates. (London: Oxford University Press, 1940.) 25*s*. net.

TELL-ED-DUWEIR is the site of an ancient city, probably the Biblical 'Lachish', on the edge of the Judæan foothills, overlooking the Philistine lowland. It was excavated from 1932 to 1938 by the Wellcome-Marston Archæological Research Expedition to the Near East, of which the late Sir Robert Mond also was an early and generous supporter. The tragic death of the director, Mr. J. L. Starkey, and the political situation, suspended the work at a very interesting phase, and even the material now in London needs much further study; but the 'Fosse Temple', lying outside the city, had been completely explored, and is now published separately, in advance, on behalf of the Wellcome Trustees. It is a fine piece of work, a worthy memorial of the able leader of the expedition—of whom there is a characteristic likeness on p. 7—and testimony to the skill, zeal, and team-work of his helpers.

Though Lachish had a long and troubled history, as one of the chief Amorite centres in Palestine, the 'Fosse Temple' only covers a few centuries of it; but they were a period of historic importance As a strong place in Hyksos occupation, Lachish had been surrounded with the rampart and fosse characteristic of its masters. With their withdrawal before the forces of Eighteenth Dynasty Egypt, this great fortress fell into disrepair; and while the Egyptian governor and garrison occupied the top of the hill, a short section of the partly silted ditch was assigned to a sanctuary, of which the furniture and ritual was Palestinian, presenting many points of comparison with the ceremonial prescriptions of *Leviticus*. It attracted, however, dedications from afar; objects of Egyptian, Syrian, and Cypriot fabrics and styles, and even a few vases of Ægean make. A fine commemorative 'lion-hunt' scarab of Amenhotep III (1411–1375 B.C.: Pl. XXXII B. 39) must have been a royal gift, and a scaraboid of his queen Tiy (Pl. XXXII B. 2) was found on the floor of 'Structure II'. For, even in its short period, the 'Fosse Temple' was twice rebuilt, and on each occasion considerably enlarged.

Nothing datable was found earlier than Thothmes III (1501–1447 B.C.) or later than Rameses II (1292–1225 B.C.), and there is ample evidence that the temple was burnt in the period of invasion and disorder in the years after 1200 B.C. The strew of vessels, bones from sacrificial animals, and other objects on the floor aud benches of 'Structure III' suggests to the excavators (p. 27) that a ceremony was in progress when the building caught fire and collapsed. But no members of that congregation perished there.

Though doubtless other parts of the site will reveal more, the contents of the 'Fosse Temple' give a vivid glimpse of the material culture of its votaries, which in many respects was high. Special attention may be called to the toilet-vessels of variegated glass, the shapely stone jugs and bowls, the beads and rich pectoral collars in glazed paste, the engraved cylinder-seals of various Syrian styles, and the wide range of pottery types, which, as usual, offer suggestive synchronisms with other Palestinian sites.

Public attention was early attracted to the two painted inscriptions on vases, in a rough approximation to the script eventually standardized in Phœnicia. Here there is a careful summary of the divergent views of experts, and some constructive criticism (Ch. iv): an amusing 'warning to epigraphists' (p. 93) is supplied by a peasant's letter to one of the excavators, actually in English and in our alphabet, but uncomfortably like the writing on the 'Duweir Ewer'. Was the spelling of the Duweir scribe as good as his script ?

Few recent memoirs in archæology have been so carefully edited and published so handsomely—or so cheaply. The photography is admirable, and the coloured plates exceptionally pleasing. Besides group-registers and inventories of the finds, there is a very useful list of the biblical passages which the 'Fosse Temple' and its equipment illustrate.

JOHN L. MYRES.

YEAST PRODUCTION

The Manufacture of Compressed Yeast

By F. G. Walter. Pp. viii+254+3 plates. (London: Chapman and Hall, Ltd., 1940.) 15s. net.

ALTHOUGH leavening agents have been known since the days of ancient Rome, it remained for Louis Pasteur to analyse their nature and to demonstrate the practical potentialities of the common yeasts. Now, in the course of a few years, as Mr. F. G. Walter tells us, the manufacture of compressed yeast has evolved from obscurity to an industry of not inconsiderable importance. The work under review has been written from the strictly technical point of view and provides an unusually readable account of the carefully controlled processes which go to the successful large-scale production of this commodity. The author's treatment is comprehensive, and affords a full explanation of the guiding principles involved at each stage of the process.

To the general biological reader the book should also prove of considerable interest in that it shows how carefully ascertained facts as to the optimum conditions for the growth of the yeast organism have been applied on a commercial scale so that maximum yields may be obtained. This, indeed, is a fascinating aspect of the subject, and one which has been handled with commendable clarity. The opening chapter deals, in sufficient detail for technical purposes, with the several species of Saccharomyces and with the undesirable pseudo-yeasts, moulds and bacteria which may vitiate pure cultures. The author then passes on to the isolation of yeasts in pure culture, the production of seed yeast, the preparation of wort, the differential fermentation of a grain brew (that is, non-alcoholic fermentation of this material so as to provide the growing yeast with a uniform concentration of nourishment), yeast production from molasses and from spirit fermentations. In each instance, full instructions are given as to the method of handling the raw materials, the timing of the process during its several phases, and the precise nature of the supervision that must be maintained.

The two concluding chapters are devoted to the preparation of dried yeast and yeast foods and to the organization and equipment of the yeast factory. In the latter, not the least important unit is the laboratory. To its equipment and to the methods of analyses to be followed the author has made appropriate references. In conclusion, the book is one which can be recommended to the general biological reader for its interest and to the technician engaged in compressed yeast production for its utility.

Pomatoceros, Sabella and Amphitrite

By Joan G. Thomas. (Department of Oceanography, University of Liverpool: L.M.B.C. Memoirs on Typical British Marine Plants and Animals, 33.) Pp. vii+88+11 plates. (Liverpool: University Press of Liverpool; London: Hodder and Stoughton, Ltd., 1940.) 10*s.* 6*d.* net.

THE Liverpool Marine Biological Committee's memoirs have proved of great service to biologists and a new volume is assured of a welcome. Vol. 33 deals with three tubicolous Polychæte worms, illustrating progressive degrees of adaptation to the sedentary habit. *Amphitrite johnstoni* lies hidden under rocky clefts and stones, where it makes a temporary burrow in the sand. *Sabella pavonina* stands upright in the mud and constructs a neat tube of selected and agglutinated mud particles lined by a smooth glistening secretion like flexible porcelain. *Pomatoceros triqueter* forms a rigid tube of calcareous matter, fixed to a rock and decumbent, the animal lying on its back within the tube. The last species is of importance to the general worker because it is used for artificial fertilization, its trochophore larva being easy to rear under laboratory conditions. Miss Thomas rightly makes it her main subject for investigation.

The anatomy, histology and physiology of the three worms have been described, and the author compares their adaptations to the tubicolous habit. Much of this has been well done and the figures are clear. There is, however, no drawing of a whole worm or even of a complete branchial crown, and the general reader who does not know the worms well can obtain little idea of their appearance. The account of Sabella is largely taken from Dr. Nicol's paper, and does not, unfortunately, do justice either to Sabella or to Dr. Nicol. Perhaps the very excellence of Miss Nicol's work made it difficult to find anything new, but this is no justification for mistakes in anatomy, such as occur in Fig. 30 with regard to the ciliated fæcal groove. In describing Pomatoceros Miss Thomas does not mention the obvious fact that the operculum has a conical calcareous top, and she omits this top from Fig. 5. Did she prepare this figure from a specimen fixed in an acid mixture? If so, why? A calcareous operculum is one of the generic characters of Pomatoceros. May we stress once more the importance of accuracy in anatomical detail as the fundamental requirement for physiological work?

Living Mathematics:

a First Year College Course. By Prof. Ralph S. Underwood and Prof. Fred W. Sparks. Pp. ix+365. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 20*s.*

THE title of this book is a misnomer. It ought to be "Lively Mathematical Writing". Witness the following extract from the authors' treatment of the method of *reductio ad absurdum*: "Having hatched up a premise which collided mathematically with its conclusions, we can announce with confidence the eternal falsity of the premise and thus get a neat headlock on reality from the rear."

Stripped of such purple patches, the journalese cross-headings, and the historical references, we are left with a text-book covering in sound fashion all the work up to Intermediate B.Sc. standard—algebra, trigonometry, co-ordinate geometry, and calculus. In addition, there is a slight treatment of elementary probability and a little elementary theory of numbers. The presentation throughout reflects the experience and enthusiasm of good teachers. There is a wealth of interesting examples, which to the more staid and restrained English teacher will more than compensate for the touches of flippancy that recur throughout the text. The book is well printed on excellent paper and the diagrams finely executed, but the result is that the price is too high for the average British first-year student.

An Introduction to the Principles and Practice of Homœopathy

By Dr. Charles E. Wheeler. Second edition. Pp. viii+344. (London: William Heinemann (Medical Books), Ltd., 1940.) 15*s.* net.

IN the second edition of this work, of which the first appeared twenty-one years ago, Dr. Charles E. Wheeler, consultant physician to the London Homœopathic Hospital and past president of the British Homœopathic Society, has received the collaboration of two other physicians to the hospital, Drs. J. Douglas Kenyon and Francis H. Bodman. The work is divided into two unequal parts. The first and smaller part, which contains four chapters, is devoted respectively to general considerations, the structure of the homœopathic materia medica, homœopathic pharmacy, potentization and dosage, and the choice and mode of administration of the remedy. The second part deals in alphabetical order with thirty-two of the drugs most frequently used in homœopathic medicine.

The work may be recommended as a useful handbook to all seeking information on the subject of homœopathy.

Naturalist Errant

Out with Romany Once More

By G. Bramwell Evens. Pp. vii+168+8 plates. (London: University of London Press, Ltd., 1940.) 5*s.* net.

MR. G. Bramwell Evens ('Romany' of the B.B.C.) not only possesses the eye of the born naturalist, which makes every detail of a ramble in the country significant, but he also evidently knows, *par excellence*, how to pick his territory; and what is more, he knows how to impart his knowledge without incurring the danger of being considered pedagogic. As we read through the chapters of this pleasant book we are, in fact, caught up in the rambles by coppice and moor, by river and rocky dell, and, almost at first hand, we make the acquaintance of merlin, raven and buzzard, stickleback and badger, heron and woodcock, and many others, the places they live in, the food they live on. It is good, racy, direct observation, packed with interest, not lacking in its philosophy, but without sentimentality. The book is attractively illustrated by line drawings and by a number of good photographs.

Biological Aspects of Infectious Disease

By Dr. F. M. Burnet. Pp. xi+310. (Cambridge: At the University Press, 1940.) 15*s.* net.

THE aim of this thoughtful, but by no means readable, work by the assistant director of the Walter and Eliza Hall Institute of Melbourne is, as we learn from the preface, to discuss the subject of infectious disease from the point of view of the biologist rather than that of the medical practitioner.

The book is divided into six parts. In the first, which is devoted to biological considerations, the ecological point of view and the evolution of infection and defence are discussed. The second part deals with "Aggressors", by which bacilli, protozoa and viruses are to be understood. In the third part the processes of defence, that is, the various aspects of immunity, are considered. The natural history of infectious disease, which includes the mode of transfer of infection, the general character of epidemics, and prevalence of infectious disease, the age incidence of infectious disease, and the general principles of their control, form the subject of the fourth part. In the fifth part certain important infectious diseases, namely, diphtheria, influenza, tuberculosis, plague, cholera and malaria receive attention. The epilogue, which forms the sixth part, contains a brief account of certain new diseases and a somewhat vague outlook for the future. It is to be regretted that the book, of which, according to the preface, the manuscript was finished by 1938, was not brought up to date "owing to the circumstances of the present time", and that there is no bibliography and only a scanty index.

Mythology of the Soul:

a Research into the Unconscious from Schizophrenic Dreams and Drawings. By H. G. Baynes. Pp. xii+939+42 plates. (London: Baillière, Tindall and Cox, 1940.) 32*s.* 6*d.*

DESPITE its sub-heading, the title of this volume is somewhat ambiguous. It might mean mythology about the soul, or mythology that is created by the soul. This is unfortunate; for a book is not seldom judged by its title. One has, however, only to open it and read through a few pages to see what its author means. Dr. Baynes is occupied with the kind of phantasy that occurs when "before the human mind had ever set itself to the labour of thought, the myth already flowed like a natural fountain out of the unconscious". These are the opening words of his introduction, and they strike the key-note of what follows.

Since Dr. Baynes is an enthusiastic follower of Jung, who broke away from the school of Sigmund Freud some time before 1914, we should expect much use to be made of the concept of the activation, in pathological conditions, of archaic contents of the "collective unconscious"; and so we do. Apart from copious quotations, particularly from the works of Jung, and a large and varied range of mythological erudition, the book consists of an account of the psycho-analytical investigation of two cases only, and is illustrated by drawings, some of them coloured, of their dreams and phantasies. In this respect it reminds one of a work by G. R. Heyer ("The Organism of the Mind") published in its English form in 1933. Dr. Baynes writes with approval of Jung's "psychological types", that is, the distinction made by him between the "introvert" and the "extrovert", later expanded by Jung himself into varieties and cross-classifications of these two basic divisions. But the whole question of "types" is at present under discussion, and has encountered violent criticism.

We have this idea cropping up in one form or another since the classifications into "temperamental types" by Hippocrates and Galen, down to the "psychological types" of Jung himself, Jaensch, Dilthey, Spranger, Klages, Gross and Kretschmer, to mention only some. But these are due to clinical observation; not all their authors are agreed in respect of the "types"; and no adequate statistical procedures have been applied (as they have in other branches of psychology) in order to establish them and verify them. This manner of treatment may suffice for the arts of medicine and psychotherapy; but it is not scientific. For the rest, Dr. Baynes's "Mythology of the Soul" makes interesting and picturesque reading, interspersed as it is with similes, metaphors, and (though sometimes rather far-fetched) analogical arguments.

Philips' Chart of the Stars

Edited by E. O. Tancock. 46 in. × 36 in. (London: George Philip and Son, Ltd., 1940.) 3*s.* net.

IN this chart the whole sky is shown on a large sheet in three sections—one equatorial, Mercator projection, and two polar maps. The stars, which are graded in size according to magnitude, including the fifth, are shown as white circles on a blue background. The chart also contains a number of the more important clusters, nebulæ and variable stars, visible to the naked eye, or in field-glasses or small telescopes, and tables supply useful information on these. Many notes are added which explain the movements of the sun, moon and stars, and also clarify certain phenomena which are illustrated in the chart. Students will find this a useful guide to the heavens.

Electrolytic Condensers

Their Properties, Design, and Practical Uses. By Philip R. Coursey. Second edition, revised. Pp. xii+190+8 plates. (London: Chapman and Hall, Ltd., 1939.) 10*s.* 6*d.* net.

THE fact that a second edition of this book had to be prepared after a relatively short time indicates its usefulness. The new edition has been slightly enlarged, the additions being distributed more or less evenly throughout the book with an emphasis on the last chapter dealing with the applications of electrolytic condensers. The preferential treatment of this chapter (increased in length by 25 per cent), especially the information given on surge-proof condensers, will be welcomed by all users of this type of condenser.

SOME RECENT ADVANCES IN DAIRY SCIENCE*

By Prof. H. D. Kay, O.B.E.
National Institute for Research in Dairying, Shinfield

Keeping Quality of Milk

During the War of 1914–18, much milk was lost, when we could very ill afford to lose it, because of souring, and much milk that did not actually go sour was rejected because it tasted or smelt tainted.

As is now well known, premature souring is almost invariably due to bacterial decomposition resulting from faulty methods of production or handling. The milk industry, both producers and distributors, have learnt a great deal as to clean methods of handling milk since 1914, and an assessment of the situation during last summer has shown that in spite of the weather, which was very favourable to bacterial growth and to souring, the quantity of milk lost was much less than that reported during the summers of 1915–1918.

The reasons for this welcome advance during the last twenty years are: (*a*) producers have been trained in methods of producing clean milk; (*b*) more apparatus and equipment for cleansing and sterilizing milk utensils are available on the farm, together with better cow-sheds; (*c*) transport of milk from producer to country and town depots has improved both in organization and speed; (*d*) methods of measuring milk quality have improved; (*e*) there has been a large increase in the amount of milk properly heat-treated before distribution.

Research into practical production methods over some years has shown that the periodic steam sterilization of all utensils coming in contact with milk is the single factor which is most important in the production of milk of good keeping quality, flavour and pasteurizability. It is one of the requirements now called for in most counties before a producer of milk can become "accredited" and share in the bonus paid for each gallon he produces.

Another stipulation for accredited milk is that the milk shall pass the methylene blue reduction test. This test, though far from perfect, is a fairly simple one, which has been improved in recent years and enables a fair assessment to be made of the bacteriological quality of the milk at the time of testing, and hence of its probable keeping quality. This test depends on the fact that, in the absence of oxygen, the presence of bacteria in milk greatly accelerates the speed at which a solution of methylene blue added to the milk is reduced to methylene white. Good milk, well produced and handled, should not reduce the dyestuff for six or more hours, whereas poorly produced or dirty milk will reduce in an hour or two, and really dirty milk in minutes only.

A similar, but from the point of view of the cheese-maker a more valuable, test for milk quality is the resazurin-rennet test. This is a test of recent origin, similar in principle to the methylene blue test, but using a different reducible dye-stuff. Here, however, a little rennet is added to the fluid, so that in addition to testing the bacterial content of the milk, its coagulability, a property of first importance in cheese-making, and one which changes for the worse with certain types of poor-quality milk, may also be assessed.

Hygienic Quality

The original reason for heat treatment of milk was the purely commercial one of so improving the poor keeping quality of the raw product that it could be handled in bulk and distributed with the minimum losses from souring to consumers in localities remote from the areas of milk production. Without such heat treatment it would be practically impossible, except perhaps in winter, to provide adequate supplies of liquid milk to our largest towns.

Under existing official regulations in Great Britain, pasteurization consists essentially in the heating of milk at 145° F. for thirty minutes. It has been shown that heat treatment under these precise conditions not only destroys the bacteria which produce souring, but also kills any disease-producing organisms that may possibly be present as a result either of disease in the cow, such as tuberculosis of the udder, or subsequent infection of the milk from human sources. But the heating must be properly done, since for the most resistant of the pathogenic organisms which may be present—that of bovine tuberculosis—the margin of safety is only some 5° and 10–15 minutes.

If the temperature of the milk is raised above 145°, pathogenic organisms are destroyed progressively more quickly, until at 162° or above their life is only a second or two. Why not, it may be asked, for official pasteurization, have a really good margin of safety and heat at 162° for half an hour? The reason is that at these temperatures the cream-line is destroyed, that is, the milk fat will not separate on standing.

* *Continued from page 45.*

During the last few years, particularly in the Midlands, an increasing quantity of milk has been 'sterilized', that is, instead of being heated at relatively low temperatures, it is heated for some minutes under pressure and at temperatures above boiling point. The cream line is certainly destroyed, and the flavour is altered to one which can be described as slightly caramelized; but the great advantage is that the milk will keep for several days, or even a week or two. It is not actually sterile in the bacteriological sense; but there are usually only a few spores left, and certainly all the pathogenic organisms are destroyed.

Officially, the words 'pasteurized milk' can only be applied to milk which has been heated at 145° F. for 30 minutes, that is, holder pasteurization. An equally effective method of bacterial destruction is to heat milk to say 162° F. for fifteen seconds, which has an effect on the flora of the raw milk similar to that of the holder method, but which can be carried out in a smaller apparatus, with much less metal, much less room, and much less time. This quicker method has been thoroughly investigated, and with modern automatic apparatus for controlling temperature and flow to make sure that no particle of milk escapes without adequate heating, it is just as safe and reliable as the holder method. An advantage, particularly in war-time, is that pasteurized milk can be obtained within five minutes after beginning the operation, instead of forty-five minutes as with the holder process. Another advantage is that whereas in the holder process there is a tendency for certain heat-loving organisms to multiply in the pasteurization plant during the run to such an extent that the flavour of the milk may be affected, and processing has to be stopped while the plant is being cleaned, this does not occur in the high-temperature short-time (H.T.S.T.) process, temperatures of 160° F. or above being too high for the reproduction of the thermophilic organisms. These organisms which are in the milk before pasteurization are largely there as a result of inefficient cleansing and sterilization of the milk utensils used on the farm.

It is clear that with this small—though perhaps not really very small—margin of safety in either the holder or the H.T.S.T. process, it would be useful if some test could be applied to the milk itself to make sure that heating had been properly carried out. True, the pasteurized milk can be tested for surviving tubercle organisms by the very delicate guinea pig test, but this test takes six weeks to carry out, and in any case the original milk before heating may not have contained tubercle organisms. For many years a suitable test was sought, without success. Some seven or eight years ago it was observed that one of the enzymes present in all samples of raw milk, phosphatase, was destroyed over all ranges of time and temperature slightly *less* readily than the tubercle organisms, so that the destruction of the enzyme meant that these pathogenic organisms had been destroyed also, and that with a margin of safety. Delicate methods of determining the presence or absence of this enzyme in milk were worked out, and now the phosphatase test, as it is called, is a very sensitive and reliable method for determining whether a given sample of milk has, or has not, been heated under correct pasteurization conditions. It is equally effective with both holder pasteurized and H.T.S.T. pasteurized milk. The test is now so precise that it will indicate with certainty in the holder process a drop of 1·5° F. in the holding temperature or diminution of ten minutes only in holding time, or a leakage of as little as 0·2 per cent of raw milk into the pasteurized bulk.

EFFECT OF HEATING ON NUTRITIVE QUALITY

A question which has caused a surprising amount of controversy in past years has been the possible destructive effect of pasteurization on the nutritive quality of milk. The discovery of the vitamins, the fact that some of them are heat labile, and the fact that milk is a fairly good source of vitamins A and the B complex raised grave misgivings in some minds as to whether milk should be heated at all, or should be drunk in the *raw* state.

In the past five or six years the problem has been thoroughly investigated under the ægis of Lord Astor's Milk Nutrition Committee, and it has been shown very clearly that the effects of modern methods of commercial pasteurization are:—no change in vitamin A; only a small destruction, less than 20 per cent, in vitamin B_1; no change in lactoflavin (part of B_2 complex); some 20 per cent destruction of vitamin C (ascorbic acid). It has also been shown that the biological value of the proteins of milk, and also the nutritional availability of the calcium and phosphorus of the milk, are unaffected by pasteurization. In addition, extensive feeding trials on school children have failed to show any difference between raw and pasteurized milk in its effect on any measurable characteristic such as height, weight, clinical assessment, dynamometer pulls, etc. Similar results have been obtained with calves as the experimental animals.

The loss of vitamin C just mentioned is not entirely due to the pasteurization process *per se*: it has been shown at Shinfield that exposure of milk in a glass bottle to sunlight, or even to ordinary daylight for a few hours, will destroy the vitamin. The blue and violet end of the spectrum is mainly responsible. Ultra-violet would probably be active, but does not, of course, penetrate ordinary bottle glass. If, during the pasteurization process, the milk is not exposed to light, there is much less destruction of this vitamin.

From the point of view of human nutrition, it is doubtful whether this destruction of vitamin C is of real importance. Cow's milk is a poor source of vitamin C in any event, and if it is used for infant nutrition it ought to be supplemented by orange juice or some other good source of this vitamin.

Sterilization causes slightly greater changes in the nutritional value of the milk than does pasteurization. A small but definite lowering of the biological value of the proteins and an increased destruction of vitamin B_1 result from commercial sterilization. Sterilization has obvious advantages in giving milk of high keeping quality, but from the point of view of human nutrition, pasteurization is the preferable process.

EFFECT OF COW'S DIET ON MILK

The really important vitamin in milk is the fat-soluble vitamin A, and its precursor, carotene (β-carotene), also present in cow's milk, from which vitamin A is formed in the animal body. Both these constituents of milk vary considerably in amount from one part of the year to another, the carotene more than the true vitamin A. The importance of vitamin A in the diet of the young growing animal is due to the facts that it is a vitamin essential for growth, and that the new-born animal has very low reserves of vitamin A in its tissues. In relation to these low reserves, it has been found that colostrum, the secretion of the udder during the first three or four days after parturition, is at least ten times richer in vitamin A than true milk. Vitamin A is colourless, but carotene is a deep yellow pigment found in all green plants in association with the chlorophylls, and is responsible for the yellow colour of milk fat and butter. During the past few years it has been clearly shown that the total vitamin A potency (vitamin A + carotene) of a given volume of mixed milk from the same herd is greatest where the amount of green food being consumed is largest, that is, when the spring flush of grass has begun. Cows are able to store some of the vitamin A they make from the ingested carotene, in their livers and body fat, and even after they have gone on to the older type of winter diet (of roots, hay, etc., containing relatively little carotene), they still continue for a while to secrete vitamin A in their milk, but less and less carotene. Later the vitamin A falls off also, and with it a part of the nutritional value of the milk. With modern conditions of winter feeding, where good quality silage, or green fodder such as kale or cabbage, or possibly even dried grass, is fed, the vitamin A and carotene content of the milk is maintained during the winter months. That a good supply of vitamin A should be present in milk is indeed more necessary for human nutrition in winter than in spring, summer, and autumn, when other sources of vitamin A can be more readily obtained in the form of green vegetables, etc.

Another important vitamin in cow's milk is vitamin B_1, or thiamin. Though milk is not a rich source of vitamin B_1, it is a source important from the point of view of human nutrition, since the volume of milk consumed is considerable, and vitamin B_1 in milk is fairly stable.

It has not been found possible to control the concentration of B_1 in cow's milk by changes in the diet. This is because the cow herself is independent of exterior sources of vitamin B_1. She can synthesize, herself, probably with the aid of the very extensive population of micro-organisms present in her rumen, all the vitamin B_1 she requires for her own purposes, and for the milk she secretes. As a consequence the level of vitamin B_1 in the milk seems to be independent of the B_1 in the diet.

With the second important water-soluble vitamin of the B group—riboflavin—sometimes called vitamin B_2—there is a definite correspondence between the amount in the diet of the cow and the level in the milk. When the cows begin grazing in the spring, the level of riboflavin in the milk rises sharply to nearly twice its winter value. As with vitamin A, early colostrum contains much larger amounts of this factor than does ordinary milk.

The vitamin D content of cow's milk varies with the diet and with the extent to which the cow has been exposed to sunlight. If the diet contains vitamin D in appreciable quantities—though there are few of the normal constituents of a cow's diet which do—then the vitamin D level in the milk is raised. The feeding of irradiated yeast or cod-liver oil leads to an increase in the anti-rachitic potency of the milk, and it has been found that commercial cacao shell meal, which contains a little vitamin D, also brings about this effect.

Summer milk and also butter prepared from such milk may contain twice as much vitamin D potency as winter milk or winter butter from the same herd. The vitamin D content of early colostrum is three or four times that of normal cow's milk.

With relatively few exceptions, of which the vitamins just described are the most important, the quality of cow's milk remains largely unaffected by the diet. Where the food of the cow is ill-balanced or deficient in some material required for the milk, for example, calcium or phosphorus or protein, normal milk continues to be secreted for a while at the expense of the cow's tissues, and then, with possibly a little change for the worse in the composition, the daily volume secreted begins to fall off more or less rapidly, or stop completely.

To sum up, milk quality is affected by a large number of factors, many of which are now known and some of which are capable of control. The dietary factors and those connected with udder disease, for example, are under fairly good control. The changes in composition due to changes in hormonal balance are at present less controllable.

Milk secretion is known to take place in the cubicle cells lining the milk alveoli in the depths of the udder tissue. All the constituents appear to be secreted at the same time by these cells; there are no specialized cells yielding protein alone, or fat alone, or water alone. This being the case, control of composition ultimately means adequate knowledge and control of the secreting mechanism of the alveolar cubical cells, which means among other things knowledge and control of the amount and quality of the milk precursors reaching these cells from the blood stream, of their supplies of hormones, oxygen, fuel in the way of glucose or lactic acid, probably also of their cellular furniture—both internal structure and enzyme content.

EARLY WORK ON PERIODIC MOTION

By A. E. Bell,
St. Marylebone Grammar School

RECURRENT events hold an interest for the human mind through their appeal to a sense of order; in no other type of phenomenon is the insistent suggestion of law in Nature of a necessity which even "compels the gods" felt so forcibly. Certainly, from the empiricist point of view much might be made of the existence in Nature of manifold periodic recurrences, and the recognition of large- and small-scale rhythms has certainly played an important part in the origins of science. Pythagoras discovered the numerical key to the periodicities of musical notes and thus the abstract idea of periodicity entered mathematics (though the origin of this idea may lie far back with the Akkadian writers of about 2000 B.C. studied by Neugebauer). By the fifth century B.C. even the non-mathematical Aristotle looked on periodicity as almost the one sure indication of necessity in natural events: the only events of which absolute necessity could be predicated were those which formed part of a recurrent series such as the orbits of the heavenly bodies.

In scientific work, oscillations which are now described as simple harmonic dominate all others, at least in their historical significance. From Galilei's discovery of the isochronism of the simple pendulum through his (probably apocryphal) observation of the lamp swinging in Pisa cathedral we may trace the development of a line of thought which has been immensely valuable in modern science. In pure mathematics the study of simple harmonic motion elucidated the interesting properties of the cycloid, whilst, through the genius of Euler and Fourier, differential equations of great generality were discovered which embraced a wide range of phenomena. Fourier's theorem, expressed in geometrical terms, indicates, through its extension to many fields, the permeation of our analysis of Nature, in the last resort, by periodicity and by simple harmonic motion in particular. The history of science is interesting for precisely this reason: it supplies a scrutiny of the origins of modern thought.

The two great reasons for the virtual absence of developments in dynamics until the seventeenth century are the absence of accurate methods of time measurement, and the teleological character of Aristotelian thought which dominated natural philosophy for so many centuries. Benedetti (1530–1590) was among the foremost of those critics of Aristotle's mechanics who paved the way for Galilei, and it is noteworthy that he adduced a certain kind of periodic motion in a straight line as a proof of Aristotle's error in supposing that anything but discontinuous motion in a finite straight line was impossible. Obviously Benedetti's thought is here scholastic rather than modern. Elsewhere he pointed out that a weight falling through the centre of the earth would execute vibrations like those of a pendulum and would not, as was essential for Aristotle's system, come to rest at the centre.

But the first recorded statement of simple harmonic motion seems to be that of Copernicus. In his great "De Revolutionibus Orbium Coelestium" of 1543 he attributed oscillatory motions of this kind to the earth's polar axis in order to explain supposed fluctuations in the rate of precession and the obliquity of the ecliptic. Here he derived linear simple harmonic motion from circular motions projected on to an axis. The term simple harmonic came later; to Copernicus such motions were *pendentibus similes.*

So early a reference to the oscillations of a pendulum as a characteristic form of motion is remarkable, for it is uniformly held that Galilei first discovered the important property of the pendulum. Favaro says Galilei noticed the isochronism of pendulum oscillations a little after 1581 and certainly before 1589. Unfortunately there is no evidence that Copernicus really forestalled Galilei, for it is uncertain that he knew that the period is (approximately) independent of the amplitude. Nor is it possible to ascribe this discovery to da Vinci. The latter made a sketch of a pendulum clock not later than 1494, but the record is very indistinct and one can infer very little from it.

A more interesting question is whether Galilei, while making the discovery, realized the errors of the simple pendulum as a method of time measure. The records of the Accademie del Cimento say that Galilei knew of the inequality of small and large swings, but he himself did not refer to it. Mersenne stated that Galilei missed the observation and regretted that he had not been "more exact in his trials". In view of the fertile ideas Galilei based on his knowledge of the pendulum, however, Mersenne's regrets appear now to have been out of place, for an exact relation between the amplitude and the period could only have been a hindrance at that stage. Galilei was able, as it was, to relate the descent of a pendulum bob with descent over inclined planes which are chords of the same circle, to indicate a method of studying fluid resistance later adopted by Newton, and to point out the problem of the centre of oscillation later propounded by Mersenne and solved by Huygens. The simple pendulum also gave him a disproof of the idea of perpetual motion and a clue to the phenomenon of sympathetic vibrations in stretched strings.

In view of all this, there is little room for regret that Galilei's trials were only approximate. Enough is known of his experimental habits to be sure that he idealized the pendulum and probably intentionally ignored small experimental deviations from formulated laws of Nature, laws which Galilei felt convinced were characterized by their simplicity. All early experiments were to some extent vitiated by the vibration of the supports or of the suspending thread. Through placing two pendulum clocks in mechanical contact Huygens discovered the effect of resonance between the pendulums, and Ellicott made similar observations independently. What is more remarkable is that Viviani, a leading spirit in the Accademie del Cimento, is credited with the statement that all pendulums deviated slowly in the same direction[1] from their original planes of oscillation. On the strength of this, Antinori and Bertrand raised the question[2] whether in fact the Italian academicians discovered and understood the Foucault effect in the seventeenth century. Bertrand implied that this was so, but that fear of the Inquisition stopped their mouths—an intriguing idea but sadly lacking in evidence.

Hooke contributed work of great importance to this somewhat neglected subject of simple harmonic motion by his statement of the essential conditions of such motions. His well-known law *ut tensio sic vis* for the extension of elastic materials indicated even to his curiously non-mathematical mind the conditions of isochronous vibrations. He saw that the fundamental condition was the proportionality of the restoring force to the displacement. On the subject of the tautochrone his theory, though far from clear, showed the force on the bob of the pendulum at any point in its path as proportional to the slope of the tangent at that point (here following Jordanus's ideas on the inclined plane). If the slope is simply proportional to the height of the point above the lowest point this amounts to a definition of simple harmonic motion. Huygens informed the Royal Society what they could not prove for themselves, that the requisite curve was the cycloid.

It appears that Huygens made his discovery in trying to obtain an expression for the period of a very small oscillation of a simple pendulum. Galilei knew the relation between the period and the length of the thread but ignored or did not know the variation with amplitude. Huygens had little difficulty in the preliminary stages. Before December 1659 he was persuaded that Galilei's theorem concerning the identity of speeds acquired in free descent over inclined planes of equal height should be applied to certain curved surfaces also. By treating a small circular arc as approximating to a parabola (with the lowest points coinciding) he showed the isochronism of small vibrations of the circular pendulum. It was only through his intimate knowledge of the properties of the cycloid that Huygens was led to recognize that oscillations in such a path under gravity would be truly isochronous; and the proof of this property of the cycloid by classical geometry was no easy matter. When he finally published his work Huygens apologized that the proof was not as rigorous as Archimedes would have desired. The proof given later (1697) by John Bernoulli to show that the tautochrone was also the curve of quickest descent was carried out by means of the calculus.

The geometrical study of the periodic motions of bodies has, however, since the time of Newton, failed to give complete satisfaction. Whether in the case of the orbits of the planets or of electrons the demand for an explanatory mechanism in terms of force and energy has been irresistible. This has meant the isolation of systems to which the conservation laws may be applied. Newton took the important step of relating accelerated motion with forces, the operation of which remained obscure, and from the work of Huygens we may trace the restricted law of conservation of energy within mechanical systems given explicitly by Lagrange[3]. When, however, we reflect on the value of this successful reduction of periodic motions to laws, we find that the gain is purely one of mathematical expression. The concept of potential energy which must be dragged in, for example, has mathematical significance but we can form no useful picture of it and indeed the 'picturability' is irrelevant. The achievement of classical dynamics was the elucidation of mathematical relationships of increasing generality between *relata* whose properties are defined by such relations. No better contrast of the attitudes of thinkers to scientific laws could be found than that of Maupertuis and Lagrange to the principle of least action. For the former, who really originated the principle, the validity of the idea afforded insight to the nature of God Himself. For the latter the principle was a purely mathematical regularity of great use in the solution of dynamical problems.

General principles were indeed essential when physicists took up the problem of the propagation of oscillatory motion in waves. Newton tried to simplify the problem of wave motion by assuming that individual particles oscillated vertically in a way comparable with water in the limbs of a U-tube, but his method of tackling longitudinal wave motion was criticized by Lagrange, who showed that Newton erred in supposing that the vibrations in the shortest path were necessarily simple harmonic. Newton proved, however, what Huygens seems to have assumed, that the velocity of propagation of longitudinal vibrations through an elastic medium was determined by the ratio of the square root of the elasticity to that of the density of the medium. Transverse vibrations, despite Newton's U-tube analogy, with one exception, never occupied the attention of the seventeenth century men of science so far as is known. The exception was the work of Brook Taylor on vibrating strings. It was not until later, however, that the theory of surface undulations was seen to have close contact with that of stationary vibrations in strings. In the eighteenth century Euler and in the nineteenth Fresnel developed the wave theory of light on the idea of transverse vibrations first suggested by Young in a letter to Arago. It is interesting that in a later letter Young harked back to Newton's idea that the law of the undulations was that of a cycloidal pendulum "which is the simplest [assumption] possible". But Fresnel rightly has the greatest honour for the development of the wave theory and also for having "impressed natural philosophers with the importance of studying the laws of regular vibratory motion and the phenomenon of periodicity in the most general manner" (Merz).

In the nineteenth century many elegant applications of simple harmonic motion were made. The invention of the Kater pendulum, Foucault's famous experiment and the work of Coulomb, Gauss and others come to mind. The study of torsion in wires was particularly useful because the torsion balance which resulted became essential in many branches of experimental work—notably in investigating the laws of magnetic and electrostatic force. Coulomb also applied the torsional pendulum to study the friction of fluids against solids.

It was, however, in the theoretical developments associated with the propagation of electromagnetic disturbances that simple harmonic motion was so important in the nineteenth century; and from Maxwell's work to the present day the concept of periodicity maintains its importance independent of the rise and fall of particular physical theories. Yet, at root, our measurement of time and our ability to recognize equal intervals appear to rest on a purely subjective sense of time's flow. Time and space as perceived are incommensurable, but are brought into relation through the geometries of four-dimensional continua; our distinction of these separate aspects of the continuum is a psychological peculiarity. This makes the mathematical measurement of time appear altogether as problematical as it appeared before Huygens brought out his pendulum clock. For the time which we measure subjectively by the pendulum may have as much relation with the Riemannian continuum as our sense of space has. It is difficult to avoid the application of the categories of experience in a field where those categories are now abandoned. Nevertheless the time-dimension, although perhaps of different character from that of Galilei and Huygens, seems to hold an increasingly important position. The new geometry achieves what was an impossibility for Euclidean geometry: the incorporation of time. With that distinction, however, the substitution of geometrical laws for those of causation is in a sense a return to the pre-Newtonian era in which the laws of the universe appeared to be purely geometrical. Truly Plato's device again appears over the portals of science.

OBITUARIES

Edward Harold Hayes

EDWARD HAROLD HAYES, who died at Tref Elury, St. Asaph, on December 4, aged eighty-six, was an able and well-known teacher of mathematics in Oxford between 1878 and 1920. A son of the Rev. William Hayes, sometime vicar of Stockton Heath, he went to Eton in 1867 and was in a Dame's house, Miss Drury's, and a pupil of the Rev. F. St. John Thackeray. He went to Balliol in 1873 as a commoner, but after his first class in Mathematical Moderations and winning the Junior Mathematical Scholarship he wore a scholar's gown.

After first classes in Mathematical Finals and in Physics, Hayes was elected in 1878 a fellow and lecturer of New College, became a tutor in 1886 and senior tutor in 1901. He gave up teaching in 1920 but remained a fellow until 1934. After his retirement he lived first in Hertfordshire and then at St. Asaph.

Hayes was an excellent colleague both as a fellow and as an examiner, and he took an active part in the mathematical teaching of Oxford. His teaching was careful and methodical, and all his pupils were well taught and some achieved distinction. He regularly attended the meetings of the Mathematical Society and produced some elegant results. For some time he was secretary of the Association of Mathematical Lecturers, before the days of sub-faculties. As an examiner in the Schools of Mathematics and of Physics he took the utmost care in framing questions and in checking results and was a first-rate judge of men's work.

When he went to New College, there were only twelve resident fellows; he shared in its growth under Wardens Sewell and Spooner, and was an efficient and able member of the College staff, and liked by all his colleagues. He took an interest in all College business but shrank from University affairs apart from mathematics; thus in 1895 he declined to be nominated as proctor. He had married Isabella, daughter of T. M. Marriott and had a son and two daughters and was very happy in his married life. Hayes's good temper and sense of humour had won him good friends at Balliol, and his story of their advice when he went to be interviewed by the New College dons as a candidate for their fellowship is characteristic. "Say nothing against the Alps to Hereford George, or against the higher education of women to Alfred Robinson, but you may say anything that you like to Spooner." Spooner would have enjoyed that story.

When Hayes retired, his colleagues parted from him with affection and respect, as from one whose humour and good sense they knew they would miss for many a day.

Mr. Heywood Sumner

We regret to record the death of George Heywood Maunoir Sumner, artist and archæologist, which took place on December 21 at the age of eighty-seven.

Sumner was a 'local' archæologist of the best type. His accuracy as a field worker and his meticulous attention to detail in recording the results of his observation with pen and pencil has rarely, if ever, been surpassed. His activities were directed mainly to the study of Cranborne Chase, of which he appreciated to the full the natural advantages that had attracted the settlement of early man, and the New Forest, which he knew in intimate detail both as a centre of natural beauty and wild life, and as a storehouse of relics of early and simple forms of social life in Britain. His book on the "Ancient Earthworks of Cranborne Chase" (1913) was accompanied by fifty maps and plans, and has been regarded by competent critics as setting a new standard in accuracy and detail for the archæologist. The same qualities for which his work on Cranborne Chase was notable were also to be observed in his survey of the Wiltshire Grimsditch, of which he published a large-scale plan, correcting an erroneous description accepted for more than a century, and the survey of the British settlement of Gussage Cow Down, which covered an intricate and obscure area of more than a square mile.

While it would be going too far to say that Sumner's work reached a limited circle only, his preference for 'local' societies, such as the Hampshire Field Club, or the Bournemouth Natural Science Society, and his aversion from any form of self-advertisement, rendered his work less widely known than it should have been before the publication in 1917 of his "Earthworks of the New Forest", in which not only did he add fifteen new earthworks to the list of those already known, but also recorded his now famous discoveries of the kilns and pottery of the 'New Forest' ware of Roman age. Here Sumner's work marked a new departure, and stimulated an interest in the work of the local potter in Roman Britain which has proved eminently fruitful in archæological study.

Sumner's further publications were a guide book to the New Forest, which has been regarded as the best ever written, and "Local Papers, Archæological and Topographical, Hampshire: Dorset and Wiltshire", containing much local lore and valuable material of archæological interest.

We regret to announce the following deaths:

Mr. Eliot Howard, a well-known ornithologist and author of "The British Warblers" (1907–14), on December 26, aged sixty-seven.

Prof. Robert Howden, emeritus professor of anatomy in the University of Durham, aged eighty-four.

Prof. D. Robertson, professor of electrical engineering in the University of Bristol, on January 8, aged sixty-five.

Prof. J. H. Smith, formerly professor of engineering in the College of Technology, Belfast, on December 24.

NEWS AND VIEWS

Cultural Treaty between Greece and Great Britain

A CULTURAL convention, the first treaty of its kind to be concluded by Great Britain with any foreign power, has recently been signed by General Metaxas, Prime Minister of Greece, and Sir Michael Palairet, British Minister in Athens. Under the Convention, the Greek Government will provide every possible facility in the future for the British Council's work of making the English language and the British way of life and thought familiar throughout Greece. From the British point of view, the principal effect of the Convention is to give full scope for the British Council's activities in Greece.

The two most important provisions are as follows: (1) The British Council's Institutes of English Studies in Athens and the provinces are fully recognized by the Greek Government, who are sympathetically considering requests for expansion. The Council's immediate plans involve the opening of ten institutes in addition to those at Athens and Salonika, and five of these are now established. The same recognition is extended to the famous British School of Archæology, established in Athens since 1886. (2) The British Council is authorized to establish two primary schools and one secondary school for British subjects in Athens and a primary school in Corfu.

The other main provisions are: (1) Exchange of university staffs and men of learning; (2) facilities for the teaching of Greek and English in either country; (3) facilities for students in either country; (4) mutual recognition of degrees or diplomas taken by Greek and British subjects in either country; (5) British students in Greece to enjoy entire equality with Greek students as regards school and examination fees, and *vice versa* in the United Kingdom; (6) mutual facilities for the import to either country of printed matter. Special exemption from tax for books supplied to the Council's Institutes; (7) students' visits to Greece and the United Kingdom are encouraged and facilitated; (8) an Anglo-Hellenic Commission to be constituted in Athens and in London, to which matters of cultural co-operation may be submitted.

Flora of Town Ruins

THE extent of building sites damaged by air raids in London, Liverpool, Berlin and other cities in belligerent countries, many of which may not be occupied until after hostilities, affords an opportunity for the botanist to observe any correlation of the famous spread of *Sisymbrium irio* over the ruins of London after the Great Fire, a rapidity which earned it the popular name of "London rocket". That there will be such a colonization by plant species even in the centres of great cities is borne out by recent studies of the flora of inner London, Liverpool, Manchester and other towns; but this points more to a predominating success of *Epilobium angustifolium*, which was not a common British plant at the time of the Great Fire although it is now one of the most abundant weeds. Observations kept on the flora of building sites in London (*Selborne Soc. Mag.*, Oct. 1910; *J. Bot.*, 1911) showed that a building site cleared in Farringdon Street and left for two years before the War of 1914–18 produced twenty-eight flowering plants and ferns, one moss and one liverwort which established themselves, comprising widely distributed plants like *Epilobium angustifolium*, *Senecio vulgaris*, *Tussilago farfara*, etc., refuse weeds and forage or packing weeds.

Wild vegetation noted on a building site in the Strand, 1929, included *Epilobium angustifolium*, *Sisymbrium pannonicum* and *Erigeron canadense*; while a 1939 survey of the wild flora of the Liverpool Metropolitan Cathedral building site, by botanists of the Merseyside Naturalists' Association, revealed forty-three species, of which *Epilobium angustifolium* was the most noticeable, others in abundance including *Senecio viscosus*, *Matricaria inodora* and *Trifolium repens*. *Epilobium angustifolium* is introduced to town sites by wind distribution of its seeds, but many plants will be introduced by birds or from seed distribution with commerce and building materials, as has already occurred on the building sites of some public air raid shelters. In the *Journal of Botany*, 1940, Dr. Ramsbottom described the introduction of the beech wood fungus, *Peziza repanda*, in abundance to London in the soil, etc., in rotting sandbags used in A.R.P.

Flora of South Albania

THERE can be few areas in Europe about which less is known of the flora than southern Albania. Large areas in the south of the country have been either wholly untouched by collectors or visited on a single occasion often only for a single day. Having regard to the richness of the flora of the Balkan Peninsula, the whole area might well be expected to yield results of taxonomic and plant geographical importance. Two expeditions made by A. H. G. Alston and N. Y. Sandwith (*J. Bot.*, May–Oct. 1940) in 1933 and 1935 have shown that the limestone mountains of the area reproduce in the main the characteristic flora of the Greek Epirus and the Pindus, and the vegetation of the higher serpentine areas is similar to that of parts of central Albania.

More than two hundred species new to the country were collected and a few new species and varieties are described. Near Moscopole two well-marked endemic species *Arenaria serpentini* and *Brachypodium serpentini* were discovered. Some notable extensions of range of previously described species are also recorded. Among these may be cited *Stachys decumbens*, previously regarded as endemic in the

Ionian Islands, discovered near Santi Quaranta; *Crepis rutilans,* formerly only known from Corfu, found between Santi Quaranta and Valona; *Cicer Montbretii,* recorded only from Thrace; *Geum heterocarpum* and *Cynoglossum pustulatum,* both new to the Balkan Peninsula, the latter previously known only in southern Spain.

Recent Additions to British Mammals

THE recent discovery of a specimen of the squirrel-tailed or edible dormouse (*Glis glis*) in Shropshire, near Ludlow (*Field*, Jan. 4) is an interesting example of an alien mammal that has colonized parts of the British countryside. Although it is a controversial point with naturalists as to whether or not established aliens and feral escapes in the countryside should be admitted to the faunal list, some recorders do accept them when they are permanently established in the wild. Some fifty years ago, the late Lord Rothschild released specimens of the squirrel-tailed dormouse, a native of south Europe, near Tring, since when it has established itself in parts of Hertfordshire and Buckinghamshire and is increasing; but the Shropshire record is apparently farther north. There are small Japanese deer established in some woods in the Home counties and Lakeland, where they are often confused with roe deer, which also exist there, while an interesting example of feral animals establishing themselves are the herds of 'wild' goats that inhabit some of the mountains of Wales, as on Rhinog Fawr, near Llanbedr, where some of the old billies have huge horns; and also in Scotland, where at least thirteen wild herds were counted a few years ago at places like Ben Lomond, at Dochfour near Inverness, on the Black Isle cliffs near Cromarty, in western Ross, Mull, Islay, Harris, Tiree, Rum, Arran and Eig. There was once a herd of feral goats on Ailsa Craig, but they were shot down because they interfered with the tame goats kept by the lighthouse keepers.

British Woodlands

PROF. A. G. Tansley discusses natural and semi-natural British woodlands in a paper published in *Forestry* (14, 1; 1940). The native British woodlands have been so largely destroyed, and existing woods are now so extensively the results of planting and replanting, says Prof. Tansley, that foresters are naturally inclined to think of them all either as plantations, or as derelict and worthless wood and scrub, of value only as possible sites for new plantations. Some foresters will think that the accusation is correct; for many quite lose sight of the value and importance of a study of the historical part of a forest region or area which may have been once afforested. Prof. Tansley traces the progress of forest destruction in Britain from Neolithic times downwards to the present day. The island climate and the fact that Britain could always obtain all she required by imports removed from us the disabilities following severe deforestation in other parts of the world.

Briefly, Prof. Tansley's thesis is that for any given type of soil the old type of forest peculiar to the soil and locality will reappear, given a chance to do so. He believes that the old forest of, say, the south of England still persists in the many examples of coppice with standards, where oak is so commonly one of the chief species among the standards; and that with the exclusion of man and his flocks, and the rabbits and hares in excessive numbers, Nature would restore in time the same type of forest as originally existed over so large a part of the country. This claim can be substantiated by careful observation, not only in Great Britain but also in several tropical countries.

Supply and Price of Bread

AN important statement upon the supply and price of bread was made by the Minister of Food in the House of Lords on December 19; it was supplemented by the chairman of the Medical Research Council. Lord Woolton said that, although we are already spending £35,000,000 in subsidizing flour generally, an extra £750,000 is to be spent in three months (as from December 1, 1940) to keep the cost of all bread at 8*d*. or less for the 4 lb. loaf. He had further decided to adopt an 85 per cent extraction as a basis for wholemeal flour, which would be supplied at the same price as what was called "national straight run" white flour (70 per cent extraction). Synthetic vitamin B_1 will be added to the white flour, but supplies will probably not be available in any quantity until May. Lord Woolton is loth to force wholemeal bread upon the public for several reasons, one very important one being the failure of high-extraction flour to keep as well as white flour. But he has been impressed by the unaninimity of scientific opinion on the nutritive value of wholemeal bread, and therefore in the printed literature of the Ministry of Food he will continue to advocate its virtues.

Lord Balfour of Burleigh said that the Medical Research Council recommends that bread should be made of an extraction of the wheat grain of not less than 80–85 per cent, and that a small percentage of calcium salt should be added to the flour. Although wholemeal flour contains more calcium than white flour, it is more essential to add calcium to the former than to the latter—an apparent paradox which both he and Lord Woolton seem to find difficult to understand. The reason is that wholemeal flour contains more phytic acid than white flour, and this acid prevents the absorption of calcium from the intestine. Lord Balfour continued that there is evidence that calcium deficiency has long been a defect of nutrition among people in Great Britain. On one point only did he disagree with Lord Woolton: he (Lord Balfour) was told that high-extraction flour, properly made, would keep suitably. In reply, Lord Woolton said that he intended to continue in ignorance of what a vitamin is, to rely upon the men of science who give him their support, and to advise the public of the results of this scientific research.

Preliminary Training for the Flying Services

THE Secretary of State for Air has announced that it is proposed to establish an Air Training Corps to provide preliminary training for men desiring to enter the Flying Services. The scheme will be divided into three parts: units will be formed at the universities, at secondary schools, and locally. At the universities, the Air Ministry is arranging a six months course for potential pilots and navigators; candidates will join the university air squadrons for instruction in service subjects, and at the same time they will attend courses given by university lecturers on mathematics and mechanics, and on either electricity and magnetism, engineering, meteorology or navigation. They will be full members of the university, and will live in colleges and hostels so far as possible. All expenses, apart from certain personal items, will be paid for by the Air Ministry. Candidates must be between 17 years and 18 years 8 months on February 15 and will be selected on nomination by headmasters; the first course begins on April 15.

Local units, for which the organization of the Air Defence Cadet Corps will be used, will be formed, and the Air Ministry is providing for lectures arranged by local authorities on mathematics and English. For the schools scheme, boys should be between 16 and 18 years of age, and they will carry out a syllabus approximating to that of an initial training wing of the R.A.F., the principal subjects being navigation, mathematics, signals and the theory of flight. Financial assistance will be provided by the State.

Sir Henry Head's Bequest to the Royal Society

UNDER the terms of the will of the late Sir Henry Head, the Royal Society is named as residuary legatee, and it is believed that a substantial sum of money will go to the Society in due course. The broad terms of direction in the will are that the money "shall be applied for the purpose of the advancement in England of the science of medicine in the widest sense"; for this purpose a committee of not less than three or more than five is to be appointed to administer the fund. Without imposing any obligation on this committee, the will suggests that the fund, or part of it, might be used to establish professorships or similar posts or research scholarships in a branch of medical science at medical or other educational institutions. Sir Henry Head, who died on October 8 last, had been a fellow of the Royal Society since 1899, and was awarded a Royal Medal of the Society in 1908.

Reading Machine for Microfilm

THE Committee on Scientific Aids to Learning, which reports to the U.S. National Research Council, is promoting, among other things, the use of microfilm, and, as a result of its efforts, a reading machine is being manufactured which will be sold at a retail price of 32 dollars. A grant from the Committee has made it possible for *Mathematical Reviews* to obtain a limited number of these machines, which will be available to those who have paid their subscriptions, at the appropriate rate, to *Mathematical Reviews*, in advance for three years beginning this month. The history of the 'reader', known as the Students Microfilm Reader, goes back to the autumn of 1939. At that time an advisory group on microphotography to the Committee on Scientific Aids to Learning, composed of Mr. Keyes D. Metcalf, director of the Harvard University Library (chairman), Profs. Ralph D. Bennett and Ernest I. Huntress of Massachusetts Institute of Technology, Dr. Vernon D. Tate of the National Archives, and Dr. Irvin Stewart, director of the Committee on Scientific Aids to Learning (*ex officio*), was requested to consider the possibilities of designing and making available a simple, inexpensive microfilm reading machine for the use of the individual student.

Eventually the Spencer Lens Company was authorized to build a model, and the Committee on Scientific Aids to Learning has now signed a contract for a number of these machines; in addition, they will be placed on the market by the Spencer Lens Company. Emphasis has been placed throughout on suitability for the purpose for which the reader was designed, simplicity and low cost. No claims are made for extreme convenience, beauty, ready portability, or universality. The Students Microfilm Reader is not intended to compete with existing reader equipment, which is generally more suited for commercial and library use. It was developed specifically to permit the individual student to utilize in his own study or laboratory microphotographic copies which he may have made personally or procured from one of the existing sources of supply. The address of *Mathematical Reviews* is American Mathematical Society, Brown University, Providence, R.I.

Developments in B.B.C. Services

NEW programmes for France and Luxembourg and an additional bulletin in Polish are included in recent developments made in the B.B.C.'s European Service (*Practical Wireless*, Feb. 1941). A Sunday programme for French listeners entitled "Une demi heure du Dimanche" which is now broadcast during 3–3.30 p.m. B.S.T., includes a review of the week's events and talks on general interest and religious subjects. It is transmitted on the wave-lengths 49·59 metres and 25·29 metres. The new programme for Luxembourg is broadcast on the last day of the month between 8.0 and 8.15 p.m. B.S.T. in the period entitled "Radio Belgique". The wave-lengths on which this transmission may be received are 285·7 metres, 261·1 metres, 49·59 metres and 30·96 metres. A third news bulletin in Polish was recently added to the B.B.C.'s broadcasts in Europe and can be heard during 4.15–4.30 p.m. B.S.T. each day on 49·59 metres and 25·29 metres.

Mr. R. C. McCall, who has been appointed to the B.B.C. staff to organize the new Pacific transmission of the B.B.C.'s Overseas Service, has recently arrived in Great Britain. This provides a further example of the close co-operation between Dominion broadcasting organizations and the B.B.C. Another similar case has been the appointment of Mr. E. L. Bushnell, controller of programmes for the Canadian Broadcasting Corporation, to the position of North American programme organizer of the B.B.C. Overseas Service and the work in Great Britain of the Canadian Broadcasting unit.

Control of Lice

IN the *British Medical Journal* of November 2, Prof. P. A. Buxton contributes an article on this subject. The crowded sleeping conditions that prevail in some of the air-raid shelters render it likely that outbreaks of body and head lice will occur. In peacetime, at any rate, the body louse is much the rarer of the two races, but it is likely to become more prevalent. At the present time no really effective practical repellent is known. The control measures advised concern the head and body and the disinfestation of clothes, blankets, etc. The best methods for effecting these processes are discussed in some detail. For control on the person the speediest method for eliminating the head louse is the use of one or other of the insecticidal liquids advised. Disinfestation of garments, etc., is best done by the application of heat: 5 minutes at 129° F. or 45 minutes at 121° F. are fatal both to the lice and to their eggs or nests. It is not important whether the heat be dry or moist; but it is essential that the whole of the infested materials should be submitted to the temperature mentioned. Disinfestation of clothes properly done with a domestic hot iron is quite effective. The organization and proper lay-out of disinfesting stations does not lend itself to explanation in a short article, and the reader is referred to the "Army Manual of Hygiene" for information on this aspect of the problem.

Spread of Desertic Conditions

MUCH has been heard in recent years of soil erosion, due to a variety of causes, emanating usually in ill-advised use of the land. In Africa this has been shown to cause the spread of waste or desertic conditions. In a paper in the *Geographical Journal* of November, on desert versus forest in Eastern Africa, Mr. E. J. Wayland points out that there are climatic deserts and climatic forests and that each will retain its characteristics in spite of man's interference; man can do little to change the aspects of such lands. However, between the essential desert and the essential forest there is forest land which on its desert side is (or was, since in Africa most has been destroyed) a zone of forest-desert equilibrium, disturbable, to the desert's advantage, by Nature or by man. This is the zone of counter forest, and on the true forest side shows a marginal belt where the forest holds as long as natural conditions have sway. In this belt, however, man-made desert is not merely possible but is very general in Africa. All African forest areas with one or two long dry seasons and a rainfall of not more than 30 inches a year may be regarded as marginal in character, and all such areas are liable to soil erosion. Mr. Wayland does not believe that desert will or can spread into the essential forest: the counter forest acts as a buffer that holds in check the spread of the desert conditions.

Prof. Eduard Albert

PROF. EDUARD ALBERT, a pioneer of modern surgery in Austria, was born at Sznfterberg in Bohemia on January 20, 1841. He received his medical education at the University of Vienna, where he studied under Hyrtl, Skoda, Brücke, Oppolzer and Rokitansky. After qualifying in 1867 he became assistant to Prof. Johann Dumreicker, professor of surgery in the Vienna Faculty. In 1872 he was appointed professor of surgery at Innsbruck where he remained for eight years and then succeeded Dumreicher at Vienna. It was here that he gained a European reputation by his introduction of Listerian antisepsis, which Dumreicher had rejected, and attracted a number of students who afterwards became eminent surgeons. Albert was well known in Great Britain, where he was elected an honorary fellow of the Royal College of Surgeons in July 1900. His principal publications were "Diagnostik der chirurgischen Krankheiten", "Lehrbuch der Chirurgie" and "Beiträge zur Geschichte der Chirurgie". He died on September 20, 1900.

Albert King

ALBERT FREEMAN AFRICANUS KING, a pioneer in malariology, was born at Bicester, Oxfordshire, on January 18, 1841, the son of a doctor interested in the colonization of Africa. At the age of ten he migrated with his parents to the United States. He received his medical education at the National Medical College at Washington, where he graduated at the age of twenty, and four years later obtained the degree of M.D. at the University of Pennsylvania. He settled in practice in Washington, where he attended Abraham Lincoln at the time of his assassination in 1865. He was for many years professor of obstetrics in the George Washington University and in the University of Vermont, which latter institution conferred on him the degree of LL.D. in 1904. He was the author of a "Manual of Obstetrics", which went through eleven editions; but he is best known for a paper entitled "Insects and Disease—Mosquitoes and Malaria" read before the Philosophical Society of Washington on February 10, 1882, and published in the *Popular Science Monthly* in September 1883, in which he gave nineteen reasons for believing that malaria is transmitted by the mosquito. He died in 1914.

Announcements

THE following officers of the Royal Society of South Africa have recently been elected: *President*, L. Crawford; *Treasurer*, R. W. James; *Secretary*, A. J. H. Goodwin; *Editor*, Mrs. M. R. Levyns; *Librarian*, E. Newbery; *New Additional Members of Council*, G. Arnold, W. F. Barker, M. Rindl.

IT is hoped to hold the first meeting of the Colour Group of the Physical Society at the Polytechnic, Regent Street, London, W.1, at 2.0 p.m. on February 12. The first portion of the meeting will be devoted to a discussion of the draft constitution of the Group. During the second portion of the meeting four short papers will be read on "Colour Tolerance".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Structure of the Sterkfontein Ape

A LARGE monograph on the South African Australopithecines is being prepared, and is well advanced; but as it cannot possibly be published, at the earliest, for some months, it may be well to give a preliminary note on two points of interest.

Recently an important paper has been published, by A. J. E. Cave and R. Wheeler Haines[1], on the nasal sinuses of the great apes. They confirm the views previously expressed by Duckworth. In the gorilla, they show that there is a large bulbous dilatation of the nasal duct; while in the chimpanzee the maxillary antrum has an extension into the palate. In the Sterkfontein ape (Plesianthropus) the antrum differs from that of the gorilla in there being no bulbous dilatation of the nasal duct, and from that of the chimpanzee in there being no palatal extension. In these two characters Plesianthropus agrees with man. Fig. 1 is the front view of a natural cast of the antrum of the type specimen, and shows its relations to the second molar tooth. The antrum is bilobate to some extent, and the intraorbital nerve passed through a canal in its upper part.

Some time ago, I was fortunate in finding at Sterkfontein a perfectly preserved os magnum. Though nearly human, it seemed unduly small, and I thought of the possibility of its being the os magnum of a large baboon. At the time, I had no baboon carpus at hand for comparison, and in the stress of other work no further examination was made. On taking up the matter recently, I was forced to the conclusion that this must be the os magnum of Plesianthropus. It cannot be a baboon os magnum. Fig. 2 shows this bone, and for comparison the corresponding bones of a large male baboon, a large male chimpanzee, a large male gorilla, and a male and female pure Bushman. In structure the os magnum of the Sterkfontein ape comes nearest to that of man. It has no close resemblance to the corresponding bones of the baboon, chimpanzee or gorilla. If the identification is correct, then the Sterkfontein ape must have had a hand not larger than that of a Bushman woman, and quite unlike those of the chimpanzee and gorilla.

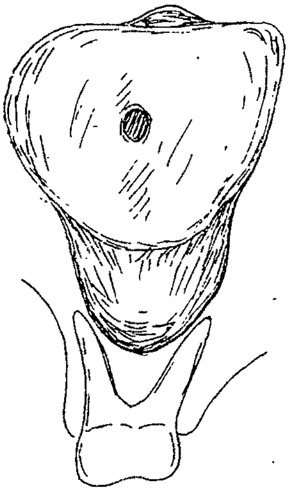

Fig. 1.

FRONT VIEW OF CAST OF THE RIGHT MAXILLARY ANTRUM OF *Plesianthropus transvaalensis*, SHOWING ITS RELATIONS TO THE 2ND MOLAR, AND THE POSITION OF THE INFRA-ORBITAL CANAL WHICH PASSES THROUGH THE ANTRUM.

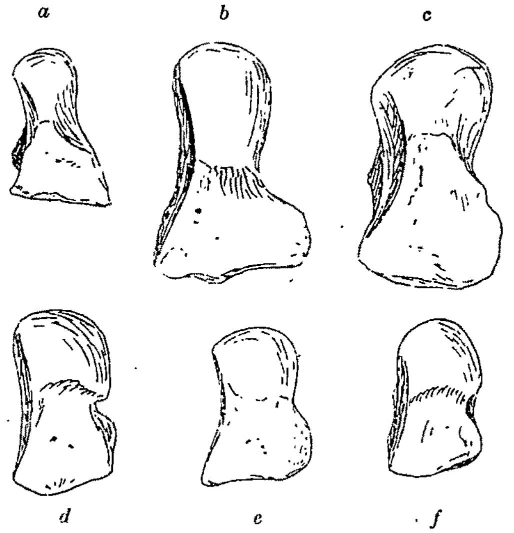

Fig. 2.

THE OS MAGNUM OF THE RIGHT CARPUS OF *Plesianthropus transvaalensis* AND OF OTHER PRIMATES FOR COMPARISON.

a Os magnum of large male baboon.
b ,, ,, of large male chimpanzee.
c ,, ,, of large male gorilla.
d ,, ,, of male Bushman.
e ,, ,, of *Plesianthropus transvaalensis*—probably female.
f ,, ,, of female Bushman.
All figures natural size.

The bone was from the same cave and from near the spot where the beautiful small female maxilla was found which I figured in NATURE of May 7, 1938. Not improbably some may argue that this small carpal bone is really human; but no other human remains have been found in the cave, nor even human implements. The maxilla has remarkably human teeth, and we need not be surprised if the being proves to have had a human hand.

If the bone belongs to the Sterkfontein ape—and I do not think there can be the slightest doubt on the matter—then we must conclude that this ape had a hand that was not much used for walking, and that Dart was probably correct in his conclusion, from the structure of the brain, that Australopithecus was mainly, if not entirely, bipedal, like man.

Rhizoctonia Rot of Swedes

IN the course of field experiments with dry rot of swedes caused by *Phoma lingam* (Tode) Desm., the presence of a different form of rot was observed on Magnificent and Tipperary purple topped swedes growing at East Craigs, Corstorphine. This rot was characterized by a slightly sunken, putty-coloured lesion, usually bearing closely spaced faint zone lines. It was readily distinguished from *Phoma lingam* rot by the absence of fructifications and the presence of a pink margin instead of a dark brown one. Such lesions were always associated with mechanical injury to the swede 'root'. The rot was comparatively shallow, dry, rather fibrous and yellowish-brown in colour.

Plentiful white mycelium grew over the surface of cut lesions when kept under a bell jar, but no fructifications were observed. Isolations from the diseased tissues consistently yielded a strain of *Rhizoctonia solani* Kühn indistinguishable in culture from those recovered from sclerotia on potato tubers.

The putty-coloured, pink bordered type of lesion was confined to the purple upper part of the 'root'. On the yellow part below soil level shallow, blackish-brown, roughly circular lesions were found from which the same fungus was isolated.

Inoculation experiments were carried out with three strains of *Rhizoctonia solani* on mature Tipperary swede 'roots' in the laboratory: (*a*) isolated from swede as above; (*b*) isolated from sclerotia on the surface of a Di Vernon potato tuber; (*c*) isolated from dead tissue below a bruise on a Golden Wonder potato tuber.

Strain (*a*) when inserted into cuts made with a sterile scalpel gave rise to rots identical with those observed in the field, namely, a zoned yellowish-brown lesion with pink margin on the upper parts of the 'root' and a blackish lesion with no distinctly coloured border on the yellow lower part. Pieces of agar culture of the same strain about ¼ in. square placed on the surface of uninjured 'roots' gave rise to no lesion.

Inoculations with strains (*b*) and (*c*) resulted in slight browning of the edges of the wound but caused no rot over a period of six weeks. Uninoculated cuts remained healthy.

About 1 per cent of the Tipperary 'roots' in the field were severely attacked by this disease.

Lauritzen[1] records a similar disease of turnips in Virginia. His strain of *R. solani* apparently differed from mine in its capacity for attacking uninjured roots.

Thomas[2] isolated four strains of Rhizoctonia from turnip in Holland, and Deighton[3] records *R. solani* attacking turnips in Sierra Leone. Hansen[4], in Norway, records infection by *R. solani* of swede seedlings in petri dishes, but I have been unable to trace any record of a swede rot in the field due to that fungus in the British Isles.

Nomenclature of Gas-Gangrene Toxins

IN NATURE of December 7, p. 748, there is a brief note on the report of the international inquiry into the assay of gas-gangrene antitoxin (perfringens)[1]. In this report, Prigge's[2] notation is used, in which the lethal factor is described as *zeta* toxin and the more hæmolytic factor as *alpha* toxin. The use of this notation is unfortunate and likely to lead to considerable confusion. The lethal factor called *zeta* toxin by Prigge is identical with that which Glenny and his co-workers[3] named *alpha* toxin in 1933, so that this usage had priority over that of Prigge by three years. During the interval, and since, a large literature has accumulated in which Glenny's nomenclature is used. It is therefore desirable to adhere to the English notation.

When in 1938 Ipsen, Sordelli and I undertook the international inquiry, it was our original intention to abide by the English method of notation, namely, to call the lethal factor *alpha* toxin and the more hæmolytic factor *theta* toxin, this last name being the one in use by Glenny for this factor in work still unpublished. For some reason unknown to me, Ipsen, who prepared our paper for publication, changed to the German notation at the last minute, and I was not aware of the change until after publication. Unfortunately, it has not been possible to communicate with Ipsen since publication, owing to the invasion of Denmark by Germany.

Magnetic and Thermal Properties of Crystalline Copper Sulphate at Low Temperatures

THE principal magnetic susceptibilities of crystalline copper sulphate ($CuSO_4.5H_2O$) have been measured from room temperature down to about 90° K.[1]. From a detailed analysis of these magnetic data, Jordahl[2] finds that they can be explained quantitatively on the assumption that the crystalline electric field in the neighbourhood of the Cu^{++} ion in the crystal is predominantly cubic in symmetry, with a small tetragonal component superposed on it. The ground state of the Cu^{++} ion is ^2D, and the crystalline field postulated is such that under the influence of its cubic part the energy levels split up into two sets, the lower set having a two-fold *orbital* degeneracy, and the upper a three-fold one, the separation between the two sets being about 18,300 cm.$^{-1}$; the tetragonal part of the field separates the levels of either set by about 2,550 cm.$^{-1}$. Each of these separated levels will have a two-fold *spin* degeneracy, which, being of the Kramers type, will not be removed by the crystalline field.

The type of crystalline field postulated above for explaining the magnetic data appears, from the known structure of the crystal[3], to be plausible. Each copper atom in the crystal is surrounded by 6 oxygen atoms, 4 of which belong to 4 water molecules forming a square with the copper atom at the centre, and the other two belong respectively to two SO_4 groups, and are located centrally above and below the square. The copper-oxygen distance for the 4 water oxygens is about 2·0 A., and for the other two about 2·4 A.

The splitting of the ^{2}D levels of Cu^{++} that would occur in the above field cannot, however, be reconciled with two important observations made recently at the Mond Laboratory in Cambridge. Ashmead[4] has observed that the specific heat of $CuSO_4.5H_2O$ shows a maximum in the region of liquid helium temperatures, and Reekie[5] has found that the effective magnetic moment of Cu^{++}, deduced from susceptibility measurements on the powdered crystal, falls rapidly in the same temperature region. These observations indicate that there are two low-lying energy levels for the paramagnetic ion in the crystal, separated by a few cm.$^{-1}$, the lower of which is non-magnetic. The pattern of splitting of the ^{2}D levels contemplated above cannot be made to conform to these requirements.

A closer examination of the structure of the crystal, however, suggests a simple explanation. The distance between the copper atom and the 4 water oxygens, namely 2·0 A., is much smaller than would correspond to an ionic binding between Cu^{++} and these oxygens, and is just the distance that one should expect for a *covalent* type of binding between them. Such a planar quadri-covalent binding is indeed common in the cupric salts[6]. Such a binding, according to Pauling's theory of directed valence, will involve the orbitals dsp^2, and the odd electron in Cu^{++} displaced from the $3d$ orbital will now occupy the $4p$ orbital. The ground state of the $[Cu(H_2O)_4]^{++}$ complex will thus be a $^{2}\Pi$ state, and the magnetic properties of the complex will, therefore, be somewhat similar to those of the nitric oxide (NO) molecule, which have been investigated theoretically in detail by Van Vleck[7] and are well known. If the coupling between the spin moment and the component of the orbital moment conserved along the normal to the plane of the complex is very weak, and of the order of a few cm.$^{-1}$ (as against 121 cm.$^{-1}$ in NO), and the antiparallel coupling between them corresponds as usual to the smaller energy, then the results obtained by Reekie and Ashmead will follow naturally.

The experimental finding[1] that the *orbital* contribution to the magnetic moment of the $[Cu(H_2O)_4]^{++}$ complex is directed predominantly along the normal to the plane of the complex is significant.

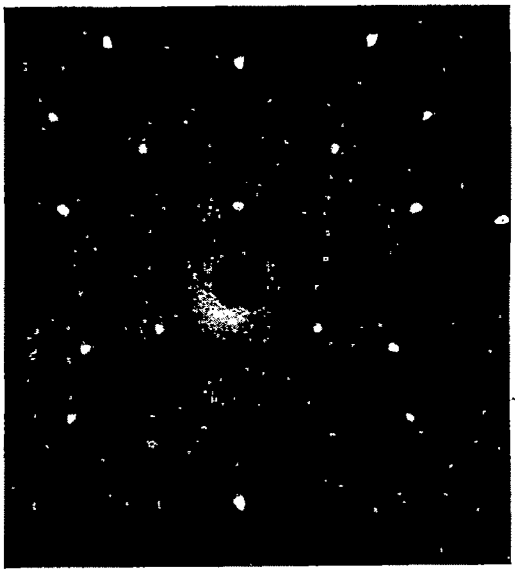
Diffuse Reflections from Diamond

Sir C. V. Raman and P. Nilakantan have published Laue photographs of diamond[1] showing modified (111) reflections, consisting of an approximately circular diffuse spot, accompanied in certain positions by two diffuse streamers, near each Laue (111) reflection. These photographs were taken with the X-ray beam parallel, or nearly parallel, to a [111] axis, a [1$\bar{1}$0] axis being vertical.

We have investigated the changes in shape of these modified (111) reflections when the orientation of the diamond crystal is varied. Perhaps the most interesting form of the reflection is obtained when the crystal is rotated about the [1$\bar{1}$0] axis, so that reflection takes place from the *other side* of the vertical (111) plane. The angle of incidence θ is $-21{\cdot}9°$ (the Bragg angle for copper-$K\alpha$ radiation), when the two horizontal trigonal axes make angles of $-41{\cdot}4°$ and $+68{\cdot}1°$ respectively with the X-ray beam, and the modified copper-$K\alpha$ reflection then forms a diffuse background to the Laue (111) spot.

For values of θ less or greater than $-21{\cdot}9°$ the modified reflection is, as shown in the photograph, a triangle of three small spots surrounding a diffuse centre. For a range of values of θ from $-26{\cdot}8°$ to $-16{\cdot}5°$, the position of the *centre* of this triangle agrees with the simple Faxén formula $d_{111}\sin(\theta+\varphi)=\lambda\cos\varphi$, where λ is the wave-length, φ the angle of reflection. The radial apex of the triangle always points away from the Laue spot, and the triangle increases in size as θ departs from the Bragg angle, although the size of the three component spots does not appear to increase. The result of this is, of course, that the $K\beta$ triangle is larger or smaller than the $K\alpha$ triangle according as to whether it is farther from, or nearer to, the Laue position. Monochromatized photographs have proved that all three spots and the diffuse centre are due to characteristic radiation (as are the circular spot and streamers of the normal orientation); while low-temperature experiments show that the modified reflections, whether of these or of other shapes given in other crystal orientations, are only slightly reduced in intensity by a lowering of temperature of 200° A., a result to be expected since the characteristic temperature of diamond is very high.



Calculations are in progress using the formulæ developed by Waller in his dissertation[2]. Preliminary results fulfil the expectation that the Faxén-Waller theory in its complete form (that is, taking into account all the elastic constants of the crystal) is capable of giving detailed agreement with experiment. In the case of diamond a triangular intensity distribution has been calculated for the special crystal settings mentioned above, the triangular spot changing its orientation in the required manner when $\theta - \theta_{\text{Bragg}}$ changes sign, whereas a more nearly circular spot is calculated for the Râman setting.

These preliminary calculations indicate that the scattering phenomenon can be developed into a useful method of determining the elastic constants of crystals. Full details will be published later.

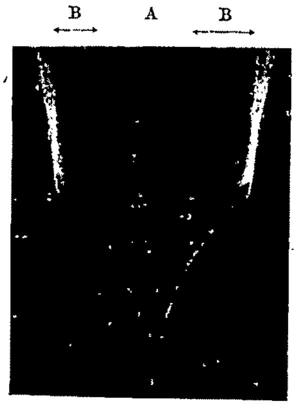
Temperature and Latent Energy in Flame Gases

THE following facts relating to the travel of flame, initiated by an electric spark, through a homogeneous inflammable gaseous mixture have been established:

(1) Flame photographs show that the flame front during the early stages of travel is of low luminosity, but later it builds up a high luminosity indicating a high instantaneous pressure and temperature.

(2) Turbulent motion of the inflammable mixture before combustion has no influence upon the rate of travel of the flame front in the early stages, but has a marked influence upon this in the later stages[1].



It seems a fair inference that, in the early stages after ignition, flame is propagated as a result of the diffusion of activated particles from the flame front (that is, by chain mechanism), but that in the later stages it is propagated as a result of conduction and radiation of heat from the high temperature flame front into the adjacent unburnt gas—or perhaps it would be more correct to say that the propagation is thermally assisted in the later stages[2].

The condition of the flame gases left behind the flame front would appear to depend very largely upon the method by which the flame is propagated. That this is so may be seen very clearly from flame photographs in which the luminosity (afterglow) from the burnt gases is registered. The accompanying reproduction is from a photograph, taken on a moving film by Mr. S. G. Richardson, of the flame front and of the afterglow of the burnt gases resulting from the travel of flame through an over-rich carbon monoxide-oxygen mixture contained in a glass tube. It will be seen that the afterglow from the gases which are first burned (marked *A*) is considerable, but that from the gases burned later (marked *B*) is very feeble. The sudden change in the intensity of the afterglow is remarkable, but it may be correlated with a sudden change in the intensity of the luminosity of the flame front, which is much more clearly shown in series of instantaneous photographs of the flame front taken by Dr. O. C. de C. Ellis[3]. Other flame photographs[4] show that the intensity of the afterglow both in the *A* gases and in the *B* gases is governed by their temperature, but the intensity of the afterglow is not generally an indication of the flame gas temperature. Indeed, as preliminary measurements made by Dr. A. S. Leah by means of thin platinum-rhodium wires have shown, the temperature of the *B* gases is very considerably higher than that of the *A* gases.

Experiments with thin platinum-rhodium wires have been made in a very long (50 ft.) steel tube of 2 in. diameter, which was filled with a thoroughly mixed inflammable gaseous mixture and ignited by an electric spark placed at the centre of the tube[5]. The temperature attained by the platinum wires after the flame had passed over them approached the ideally calculated temperature for the gases when the wires were placed some distance away from the spark, but over the first 9 in. from the spark the wire temperatures measured were as shown below:

Distance from spark in inches	1½	8	9
Wire temperature, °C. ..	1570	1750	1810

It will be noticed that at 1½ in. away from the spark, at which point the flame gases probably resulted from a combustion propagated purely by chain reaction mechanism, the temperature of the wire was only 1,570° C., whereas at 9 in. away it was some 240° C. greater. Previous experiments reported[6] have led to the conclusion that the temperature of the flame gases resulting from the combustion of an inflammable gaseous mixture increases, and therefore the latent energy contained in them decreases, as the distance of flame travel from the igniting spark increases. The experiments now described give further support to this conclusion, and suggest that this is because in the early stages of combustion after spark ignition the mechanism of combustion differs from that in the later stages.

Bunsen burner flame gases result from combustion, the propagation of which is thermally assisted. Their temperature is therefore greater than that in flame gases resulting from combustion in the early stages after spark ignition.

RESEARCH ITEMS

Origin of the Pentatonic Scale

THE late survival of a manner of life belonging to the Early Iron Age in the Hebrides has suggested to E. Cecil Curwen a study of the origin of and distribution of the pentatonic scale (*Antiquity*, December 1940) which occurs there in folk-song as, it was supposed, a unique instance in Europe. An examination of various collections of folk-songs showed that the scale of five notes occurred as a tradition strong in Scotland, fairly strong in Ireland, but weak in Wales and England. The scale of six notes (hexatonic), however, is almost as strong in England and Wales as in Scotland and Ireland. Western Europe (Brittany, France, Basque) is weak in pentatonic but still strongly hexatonic. In northern Europe there is a heavy concentration of pentatonics in the extreme north (Lapland), fringed by a moderately strong pentatonic tradition in Finland, the Faroes, and perhaps northern Russia. Farther south, pentatonics are weak, hexatonics numerous, except, possibly, in Germany. Fewer melodies have been acquired in southern Europe. Pentatonics seem to be confined to Greece and the Balkans, hexatonics here, too, being numerous, but weak elsewhere where the heptatonic scale prevails. Outside Europe the tradition is: Arab, highly developed heptatonic; India, heptatonic with an earlier pentatonic co-existing, and associated with a pre-Aryan population; Persia, resembling Hindu. This suggests a possible correlation between heptatonic scales and Indo-European languages. Elsewhere in Asia, pentatonic scales are common if not predominant—Mongolia, China, Japan, Siam, Annam, Java, also South Seas, New Guinea. In America and Africa, pentatonics are common or have been widely reported. This distribution suggests that the area covered by the Indo-European languages forms an island of heptatonics surrounded by an ocean of earlier pentatonics. The latter is vocal rather than instrumental, while the heptatonic is an instrumental scale and its distribution is a measure of the spread of harp, lyre or flute. These are considered to be of Asiatic origin, the harp appearing so early as the close of the fourth millennium B.C. (Jemdet Nasr). The heptatonic scale is therefore one of the arts of material civilization appearing with agriculture. In the process of diffusion from the East, it probably reached Great Britain in the Late Bronze Age with the Celtic intrusion, where it impinged upon a population descended from the neolithic megalith builders who had spread along the shores of the Atlantic and formed a pre-Celtic, prehexatonic population, possibly to be identified with the Picts.

Social Organization of the Haisla, British Columbia

THE Haisla, who occupy the upper reaches of the Douglas Channel, with Tsimshian, Kemano-Kitlope and Haihais as their nearest neighbours in the maze of channels east of Princess Royal Island, were visited in 1935 by an expedition under the auspices of the University of California with the assistance of the Social Research Council. Ronald L. Olson, in reporting on their social organization (*Univ. California Anthropol. Rec.*, 2, 5; 1940), appends notes dealing with the Kitlope (Kemano) tribe. The Haisla and Kitlope alone of the Kwakiutl-speaking tribes have a full-fledged maternal exogamic class organization. They say that the Haihais and Heiltsuk do not know how to marry, as they originate from a girl who "married" a dog. The Haisla have six clans, each named after an animal. Although the clans act as units in everyday matters, in most festivals (potlatches and feasts) they are (except for the Eagle) linked with one or more of the other clans. Clan affiliations and rank are of the utmost importance—even more important than the biological family. As the clan occupies one village only, village grouping is of no importance. There is no trace of a formal moiety organization, except for a curious institution among the boys. A line through the centre of the village divides the boys into two groups, regardless of clan. Anyone crossing the line alone is liable to attack. On occasion they line up for sham battles. This rivalry is encouraged by the elders. Each clan has a number of crests, as, for example, in the Eagle clan—eagle, sea otter, ermine, owl, shag, a creature like an eagle with down-turned beak, hawk, halibut. This clan is sometimes termed Owl. The titles of nobility or rank are as carefully guarded and kept as the crests. They are variable in number for each clan, some belonging to men, others to women. Some of the higher chiefs have one or more "seconds" or helpers whose title may be rendered as "speaker". Though commoners and never chiefs, they are highly respected. Only the highest chiefs may have speakers, and they must be of the same clan. The office is inherited in the same way as other titles through the sister's son.

Early Growth of the Human Skull

IT is a matter of common observation that at birth the human head is still in a plastic condition—certain races take advantage of this to produce deformities—and that until it becomes finally fixed in the adult condition it undergoes unequal growth in different dimensions. These changes have been fully studied by means of a series of measurements, and the results analysed statistically by C. B. Davenport (*Proc. Amer. Phil. Soc.*, **83**; 1940) on a full series of subjects. Apart from the detailed measurements which are given and illustrated by 170 growth-curves as examples, several general conclusions arrived at by the author are not without interest. First, due no doubt to the plasticity of the skull at birth, is the fact that environmental conditions play an important part in determining the final head shape. The changes in the proportions of the head are most marked in the first few weeks after birth due in part to the deformation caused by birth itself. Gravity has a flattening effect, which is noticeable as the child begins to sit up and to walk. Absolute cephalic measurements are less in the female than in the male in relation to her smaller size, and the mean cranial capacity is less in girls than in boys absolutely and in relation to stature and body modulus. The growth-curves of the heads of three pairs of monozygotic twins show that, while in each pair they may lie close together or sometimes apart, they run in parallel courses. In similar curves of dizygotic twins no such correspondence is exhibited. Negroes have the greatest head-length and head-girth, while Nordic children have the largest post-auricular head segment and the largest height/length ratio.

A Study of Bird Migration

Too often in discussing bird migration use is made of general and somewhat nebulous observations which do not provide ground for arriving at satisfactory conclusions. James Ritchie (*Proc. Roy. Soc. Edinburgh*, **40**; 1940) has furnished an example of the other method of approach by analysing, so far as possible, conditions associated with the appearance of an exceptionally large number of waxwings (*Bombycilla garrulus*) in Britain in November 1921 and checking this up with the corresponding records of the arrival of the same flights in Denmark. Accepting the not unreasonable assumption that the birds flew south at an average rate of twenty-five miles an hour and started in southern Scandinavia, as local records suggest, an explanation of their appearance in Britain can be given in terms of the direction and speed of the wind during the migration. This was generally one day later than the corresponding flights arrived in Denmark owing to the greater distance to be traversed. The author accepts the general proposition that the fundamental impulse to migration is associated with the reproductive cycle. He suggests that the birds tend to take off into the wind, so the direction of the wind may be a factor in determining the actual time of starting. In general, too, the migration took place in normal temperatures for the time of year following a sudden temporary drop and as a rule on cloudy or overcast days. It is suggested with regard to the latter conditions that they may enable the lung surface to keep moist without undue loss of the body water on a long-sustained flight.

Formation of Sand Cays

IN a paper on sand cays and their problems in the *Geographical Journal* of November, J. A. Steers traces the probable growth of these coral islets. The growth of the reef corals, the erosive action of waves in piling up blocks of coral rock, and the chance of seeds arriving and germinating are all familiar factors. He stresses, however, two other agencies in the growth of cays. Calcareous algæ, especially Halimeda, help in the formation of sand which adds compactness and solidity to the loose formation and so prepares the ground for wind-carried seeds of higher plants. This action is explained at greater length in a companion paper by V. J. Chapman. The second process in stabilizing the cay, and one that Mr. Steers regards as of great importance, is the formation of beach-rock. In tropical waters a great deal of calcium carbonate is precipitated on or just beneath the surface of beaches and has the effect of cementing the sand into hard surfaces like paving stones. These slabs dip with the inclination of the beach. Their formation is limited to a small vertical range which is governed by tidal range and wave action. In Jamaica the range is three feet; in Australia it is four feet. It is generally formed in patches and seldom encloses a cay. Its formation seems to depend on many factors, and possibly the presence of vegetation may be a factor. Once formed it protects the cay from wave action and encourages the growth of vegetation. But since it is rarely peripheral, wave action gets between and behind the slabs, and lines of beach rock may lie well away from the cays; some even lie at right angles to the shore of the cay.

Dipole Moments of Substituted Benzoic Acids

THE direction of the group moment associated with the carboxyl group has been considered by C. S. Brooks and M. E. Hobbs (*J. Amer. Chem. Soc.*, **62**, 2851; 1940) in connexion with measurements on benzoic acid and some *para-* and *meta-*substituted halogen benzoic acids. Since the acids are normally associated even in dilute solutions in benzene, dioxane was used as the solvent. The mean direction of the carboxyl group moment was calculated as 74° with respect to the C-C line. No conclusion could be reached as to free rotation, as the values are compatible either with free rotation or with an equimolecular mixture of molecules in which the carboxyl group is fixed in the plane of the ring with the O-H in *cis-* and *trans-*positions, respectively, with respect to the *meta-*substituent in the benzene ring. A small discrepancy between the expected and observed values of the moments of *p*-chlorobenzoic acid and *p*-bromobenzoic acid is attributed to a resonance effect between the halogen and carboxyl groups in the benzene ring.

Monochromatic X-Rays

THE production of X-rays is always highly inefficient, since the greater part of the electrical energy put in is lost as heat. Even so, the product is still chromatic. When monochromatic radiation is needed, the inefficiency is still greater. R. Q. Gregg and N. S. Gingrich have reported (*Rev. Sci. Instruments*, October 1940) an interesting experimental comparison of the use of crystal-reflection and of filtration to get a monochromatic beam of molybdenum $K\alpha$ radiation ($\lambda = 0{\cdot}708$ and $0{\cdot}712$ A.). Although their special interest was in the X-ray diffraction patterns of liquids, the results are applicable to all work for which monochromatic X-rays are essential or desirable. In one set of experiments, using a General Electric Co. Mo-Target tube with an applied peak voltage of 37·0 kv., the diffraction patterns of liquid sodium were got after the original radiation had been reflected from calcite or from rock salt crystals, or after it had been filtered through various thicknesses of zirconium oxide with or without the addition of aluminium foil. The actual times of exposure used to blacken photographic film varied from 11 hours, when the direct beam from the X-ray tube was used, to 162 hours, when calcite reflection was used. When the times of exposure were reduced to times needed to produce an image density of 1, the differences were strikingly illustrated. Thus, the times were, for no filter, 8 hours; with rock salt reflection, 58 hours, and with calcite reflection, 356 hours. The general conclusions are that under these conditions calcite reflection is impracticable, that short exposure times can be obtained by using impure radiation, but that none of the reasonably satisfactory degrees of filtration is any more expedient than the use of rock salt reflection. The dangers of using partially filtered X-rays where a monochromatic beam is needed are well illustrated in graphs showing how an entirely spurious peak may appear on the intensity curve of the diffraction pattern.

RAILWAY RATIONALIZATION

ALTHOUGH railway speeds in Great Britain are generally good, the average speed at which a traveller could accomplish a series of random journeys by rail is likely to prove very disappointing. No doubt, many passengers ask themselves if something better were not possible, but seeing no solution to the problem, accept the position as inevitable. That it is a state of affairs which can be improved by a rational system of reorganization, leading possibly to the doubling of the average speed, is the contention put forward by Mr. J. F. Pownall in a booklet entitled "New Railway Network Principles" (Birmingham: Cotterell and Co. 2*s*.). This contains the gist of the chapters of a book dealing with one of two projects relating to waterways and railways in Great Britain which have had to be set aside to await the advent of better days.

Now, however, is the time for such ideas to be broadcast so that when these better days come we may be prepared to make such changes in our present system as will restore the railways to the position they once held in the estimation of the public. The author has taken a journey of 2,342 miles, from one town to another and then to a third and so on, and finds from "Bradshaw" that the average speed works out at 16½ miles an hour. His method of improving this is based on an ideal network of equilateral triangles of 50 miles side, and along the sides of these triangles fast trains would start precisely at each hour and arrive 52 minutes later. This gives 8 minutes at each junction for changing if necessary. Slow, stopping trains would also run, taking about two hours for the same journey, and by their means a traveller starting from an intermediate station travels at about 25 miles per hour to the first junction, then on by fast trains at 50 miles an hour, and lastly to an intermediate destination by a slow train at 25 miles per hour.

Turning then to the practical application of this ideal system, the author shows that by certain modifications of the present lines a workable system of railway operation can be developed so that the original series of journeys could be accomplished at 31½ miles an hour, or in a total time of 74 hours instead of 142 hours as planned from "Bradshaw". This remarkable saving of time is but one—the principal one—of many advantages of the system. Another is the simplicity of time-tables, since trains would always start from the junction stations precisely at the hour and from intermediate stations always at a fixed number of minutes after the hour.

The fast and slow trains referred to are in addition to the main line expresses, and thus, if any substantial part of a journey such as that described followed these main lines, a further saving of time is probable. A similar scheme is put forward for the improvement of goods traffic on the railways, but when the author suggests that the loading gauge should be made considerably larger than at present, he enters upon a phase the cost of which would almost certainly heavily outweigh the advantages it would confer. Many of his proposals are, however, quite feasible and only need a change of outlook from our present markedly conservative one. The new type of junction station, the standardization of trains, the co-ordination of rail and road services, and many other details deserve—nay, rather demand—from us all very careful consideration and thought, for, when all is said, the scheme involves a revolutionary change of mind as to the place of railways in our mode of life.

A.R.P. COMMUNICATION

W. P. WILSON describes in the Engineering Supplement to the *Siemens' Magazine* of November the A.R.P. telephone and signalling system, A.R.P. (No. 186) devised by Messrs. Siemens. One of the essentials of any system is the provision of a trustworthy method of giving the various signals required, and maintaining rapid communication between the personnel concerned. For obvious reasons it is not desirable for private A.R.P. organizations to use sound signals; it is usual, therefore, to employ bells or buzzers and visual lamp signals of various types, communication being maintained by a suitable telephone system.

In some cases existing private telephone systems can be used or adapted to meet the conditions, but it is generally found that a separate system designed to meet the special conditions is the most desirable. This is particularly the case where large schemes are concerned. In such instances it is usually advisable to supplement any existing telephone system by an entirely separate emergency scheme in order to safeguard against the failure or destruction of the regular telephone system.

The mere knowledge of the existence of a reliable communication system greatly assists in dispelling feelings of isolation or panic on the part of the staff of the organization concerned. One of the essential things to consider in connexion with a communication system is the probable short time available for taking action after the receipt of a warning. This is particularly the case under the recent arrangements of the 'spotter' system. Communications include both telephone and signal systems, the former to provide complete control of the A.R.P. personnel, and the latter to indicate clearly to the whole staff the action to be taken.

The telephone system, which should be planned to meet individual requirements, should be easy to operate and also to repair. For most cases a simple system of magneto telephones is believed to be the best. Magneto telephones are self-contained units, each has its own ringing apparatus and its own battery for supplying the speaking current, thus eliminating the risk of breakdown due to the failure of a central battery. Further, two or more magneto telephones can be connected together at the control board, and they can then ring each other direct without the assistance of an operator. If the control board is put out of action the line wires can be quickly connected so that the telephones continue in service by means of code rings. This is not feasible with central battery sets.

The telephones recommended are equipped with powerful magneto-generators and high-resistance bells, enabling a number to be bridged across one pair of wires if desired. They are fitted with 'neophone' hand-microtelephones to improve speech transmission. Portable telephones are provided for by 'looping in' one pair of wires at each point and fixing a 2-pin weatherproof socket. A lamp calling-system in addition to the bell can be fitted when the telephone is to be used in a very noisy position.

A.R.P. signals can be either visual or audible or a combination of both. The signal system usually consists of a starting switch which puts into action loud-ringing bells, hooters, etc., where large staffs are to be controlled, and buzzers or single lamps for offices and small staffs.

AN EXPERIMENT IN BIOLOGICAL CONTROL

THE control of injurious forms of insect life by the application of biological methods has, in a number of instances, proved remarkably successful. Other methods of control in such cases had been of little avail or were impracticable. Success achieved by the utilization of the natural enemies of injurious insects has usually proved to be relatively inexpensive and of a more or less permanent character. As a rule the most favourable conditions are those afforded by tropical or subtropical islands where the dissemination of the beneficial introduced insects meets with few handicaps or barriers. Recently an experiment in the biological control of coconut pests in Seychelles has been recounted (*Bull. Entomol. Res.*, **31**; 1940).

The author of the paper in question, Mr. D. Vesey-Fitzgerald, mentions that the affected crop is of special importance, since its product, copra, is the main export of Seychelles. The pests concerned are scale insects (*Coccidæ*), and of these, four species were specially injurious. It is noteworthy that the species in question, namely, *Ischnaspis longirostris*, *Pinnaspis buxi*, *Chrysomphalus ficus* and *Eucalymnatus tessellatus*, are unknown as major pests of coconut in other countries, while the brown scales, that are usual pests of this crop, are not found in Seychelles. Other Coccidæ were also found to be infesting coconut in this area, while a large variety of different species were noted as attacking the general vegetation.

This fauna needed investigation, as it concerned the main problem, and as a result it became evident that general rather than specialized enemies of Coccidæ required searching for. Species that would, in fact, attack all the different scale insects without special preference were obviously needed, since the elimination of a particular kind might result in an increase of some other species. The life-history and special requirements of each of the four species, already named, are described and their incidence on the coconut is discussed.

In order to combat these Coccidæ, four species of Coccinellid beetles were introduced from East Africa. The species were *Chiloconus distigma*, *C. wahlbergi*, *Exochomus ventralis* and *E. flavipes*. Since the journey from Mombasa to Seychelles takes only three days by steamer, these predators could be landed there within a week of leaving the centres where they were bred in East Africa.

The breeding technique and the establishment of each of these species is dealt with. Records covering three years are given in order to show the effects of the introduced predators on the population of scale insects. The figure quoted shows that the introduced enemies are reducing the scale insects below the density at which they cause economic loss. Also it seems that the reduction of one species of pest has not been followed by a correlated increase of another species.

ELECTRICITY IN AGRICULTURE

REFERENCE has already been made in NATURE (Jan. 11, p. 62) to the report on the utilization of electricity in agriculture and horticulture prepared by C. A. Cameron Brown and issued by the Electrical Research Association. The Instit [illegible] Engineers is now publishing wri [illegible] to the discussion of this report. Th [illegible] appears in the Institution's *Journ* [illegible]

Mr. H. W. Grimmitt, of the st [illegible] drive, and there is evidence of enthusiastic co-operation from the agricultural research institutions and also from the Ministry of Agriculture and the Agricultural Research Council. As a preliminary to [illegible] E.R.A. has had prepared a com- [illegible] whole field of research on the [illegible] nation on past work [illegible] for future work. [illegible] investigate by wages, etc., have, as in many other branches of farming, lent greater weight to any considerations of labour saving or the obtaining of first-class results with comparatively unskilled or newly trained labour. The mechanical milking machine is an outstanding example of such a case. Americans are definitely in favour of milking machines, largely because of the labour-saving aspect. Official figures show an average increase of 112·7 per cent in the output of milk per hour of labour and, in all, a labour-saving of 52·1 per cent.

Cooling the milk after milking is another vital step in the process which does not always receive the attention it deserves. Here again, electricity is the best source of power, with attractive characteristics to the supply authority, the connected load being from ½ to 1 horse-power, and the return some 500 to 1,000 kwh per consumer per annum for a 30-cow herd.

Water supply is second only to field work in essential importance on the farm ; on the dairy and stock farm it might almost be awarded the premier place. The tendency is still to make a simple substitution of an electric motor for the previous source of power, in ignorance of the increased opportunity afforded by electrical operation and of the great advances made in recent years. The most notable has been the perfecting of the small automatic air-pressure controlled set ; the full utilization of this method of water supply gives all the advantages of main water supply but at a substantially reduced cost.

A vital requirement on a dairy farm is the provision of hot water and steam for the essential washing and sterilizing of dairy appliances and utensils. There is no technical difficulty in doing this electrically, and to the electrical industry it is a very attractive load. On an average farm the washing and sterilizing requirements alone could account for a consumption of 500–1,000 electric units a year.

On the poultry farm, too, electricity can play a substantial part.

For several purposes, the use of power for grinding mills and general farm-yard loads is used extravagantly on many farms at present. For example, a grinding mill taking anything from 5 h.p. to 15 h.p. may be used for only a few hours weekly. By suitably using a much smaller mill of a simpler and more foolproof type and leaving it to run all day and all night if required, the power requirements may be reduced to about one fifth of what they were before for the same amount of total work. In threshing, the traditional method of using a large thresher requiring about 15 h.p. could be modified to enable correspond-ing work to be done over a long [illegible] reduction of about 50 per cent i [illegible] To the farmer the at [illegible] bugbear of pro [illegible] removed as h [illegible]

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Monday, January 20

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir David Chadwick : "Some Problems of World Economic Development" (Cantor Lectures, 1).

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Commandant J. Hackin : "Routes anciennes en Afghanistan".

Tuesday, January 21

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Dr. Gilbert Murray : "Hellenism".*

WARBURG INSTITUTE (at the Imperial Institute Buildings, London, S.W.7), at 2.30 p.m.—Dr. O. Kurz : "Stellar Divinities in the East and the West".

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 1.30 p.m.—Mr. Herbert Cecil Whitehead : "The Design of Sewage-Purification Works".

Wednesday, January 22

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir Alan Cobham : "Flight Refuelling".

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Mr. Frederick Chapman : "On the Sequence and Age of the Rocks in Borings in the Atoll of Funafuti". Dr. A. G. Jhingran : "The Cheviot Granite".

Saturday, January 25

INSTITUTE OF PHYSICS (London and Home Counties' Branch) (at the Research Laboratories of the General Electric Co. Ltd., Wembley), at 2 p.m.—Conference on Industrial Radiography (Chairman : Dr. V. E. Pullin). Mr. H. P. Rooksby and Miss K. L. Jackman : "Applications of Radiography to the Electrical Industry" ; Mr. W. L. Harper : "X-ray Examination of Light Alloy Castings" ; Dr. L. Mullins : "Recent Developments in the Photographic Aspects of Radiography".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned :

LECTURER IN COOKERY AND DIETETICS to the Liverpool Education Committee—The Director of Education, 14 Sir Thomas Street, Liverpool 1 (January 22).

TEACHER OF SPEECH TRAINING in the Aberdeen Education Committee's Schools—The Director of Education, Education Offices, Municipal Buildings, Castle Street, Aberdeen (January 25).

[illegible] in the Leicester Education Committee's Schools [illegible]cation, Education Department, Newarke Street, [illegible]

[illegible]EACHERS to the Bradford Education Committee [illegible]cation, Town Hall, Bradford (January 25).

[illegible]MATICS at the North Staffordshire Technical [illegible] Governors, Town Hall, Hanley, Stoke-on-

LEADERSHIP IN CIVIL DEFENCE

IN the searching ordeals of bomb and fire through which one after another of our great cities have passed, the fortitude and courage of their citizens has time and again overshadowed material destruction. Few can pass along those stricken streets without being inspired by the capacity of men and women to rise above discomfort, sorrow and heavy loss, or without viewing in the splendour of the human spirit revealed alike in the work of civil defence, or of caring for the homeless and suffering, an earnest of our powers to build better when the opportunity comes. The unconquerable spirit revealed in the address of the City Architect of Coventry before the Royal Society of Arts early in December attests that the opportunities are already realized, and that out of the present evil, as from a forest fire, may come greater riches and beauty.

The patient heroism and stedfast service which so many citizens have displayed in these days of trial should not lead us to imagine that all is well, even in the human element. The reports of the Horder Committee show how much still remains to be done for the safeguarding of health in public shelters, and in the repair of ravages in the welfare services. Education itself is a victim of air warfare which even yet has shown no sign of approaching convalescence. The extension of the principle of compulsory fire watching is itself a reminder of a field in which there has been the gravest dereliction of duty both by corporations and by individuals.

The response to Mr. Herbert Morrison's appeal for the immediate formation of fire-bomb fighting parties in business and residential districts shows that the ordinary citizen is now fully alive to this particular danger and is eager to play his part. It may be true that in Great Britain we must have experience before we do our best. Even the stern teaching of the school of fire precautions in London was ignored by many until the lesson was learned in their own hard school. That the lesson has been well learnt has since been shown by recent experience in Cardiff, Bristol and elsewhere.

In spite of this national failing, it is not with the individual citizen that the chief weakness or danger lies, whether in this matter of fire-fighting or other questions. That lies rather in the failure of the Government to use to the full the wide powers with which it has been entrusted, and in the absence of real leadership which has characterized both Government policy and local authorities in various fields. Few as may be those who seek to evade their responsibilities and duties, unless the Government is prepared to deal with the offenders in such matters as fire-fighting, the training of labour, the evasion of rationing, neglect of cultivation, to indicate only a few widely differing fields, the defection of the few may involve the whole community in severe suffering and hardship.

If, therefore, the amended Fire Watchers Order is to prove adequate, there must be no failure to enforce it by stern penalties where necessary. Weakness at this point may invalidate the efforts of the many and defeat the purpose of the whole organization for dealing promptly and efficiently with the menace. It is always at its weakest link that the chain is tested. Evidence that the Government was determined to act vigorously in this matter where required and prepared to institute the necessary inspectorate to collect any evidence of neglect would have a moral effect reaching far beyond the field of fire-fighting.

No less important, however, is the question of leadership or direction. Unless that is wise and effective, the fullest use cannot be made of the zeal and courage and heroism of the individual, either as the private citizen or as a member of the civil defence services. There is lamentable evidence that damage has been done which could have been prevented because fires were not tackled rightly at the start, and because no one in the area had been made responsible for judging what kind of a fire it was, its peculiar dangers, and for seeing that the proper number of machines was there. In fire-fighting no less than in other warfare, there must be efficient command.

It is no fault of the Auxiliary Fire Service that its firemen are not strategists and that its own officers lack the experience of the long-trained fire expert. Something must be done to supply the necessary direction to this valuable and immensely willing force. Adoption by all cities and towns of the London practice, according to which all fires in a defined area are watched over by a senior officer in control of fire, has much to commend it. This officer patrols round them, directing operations, giving advice, and is expert enough to know what assistance may be needed. If junior officers accompanied him, this strategist might even run a school for strategy.

A major purpose of the Fire Watchers Order is to increase the efficiency of the fire services, setting them free to concentrate their energies, by the systematic prevention of unnecessary fires. It should be a first duty of the new fire prevention executive to increase that efficiency from the other side by strengthening command and strategy. Nor is it only in the field of strategy that command needs strengthening. The neglect of the firemen on duty has been a most lamentable feature of more than one of our great cities in their recent ordeals. Admirable arrangements for caring for the homeless by the provision of accommodation and meals have existed side by side with a scandalous neglect to provide rest or food for the men continuously engaged for long hours in bringing the fires under control.

There is, indeed, unmistakable evidence that some fire organizations and the authorities controlling them have yet to learn what is really implied by Napoleon's dictum that an army marches on its stomach. Neglect of the physical welfare of the auxiliary firemen may be as detrimental to the efficiency of the fire-fighting services as the absence of strategy, and is an equally damning indictment of the command. What is more, it is deeply resented by the many citizens to whom it has been obvious in recent weeks, and who to their honour have sought by private generosity to repair official neglect.

These are among some of the matters to which Mr. W. S. Morrison and Sir John Greenly may rightly be expected to give their attention when they have selected the personnel of the new fire prevention executive, if there is not in the meantime a speedy improvement in the situation. Important as they may be, they are, however, only mentioned here as illustrations of the damage which defective command or inefficient administration may do to the national effort. Administrators who are unequal to their task must be removed from office as ruthlessly and unhesitatingly as generals or admirals or air-marshals whose powers have been overtaxed by command.

It will be well, therefore, if deficiencies in direction, and command which have been revealed in our civil defence services by recent events stimulate further attention to this vital matter of leadership. The consequences which can flow from defective leadership, whether through lack of vision or organizing capacity, or administrative inefficiency, are too far-reaching to be disregarded. They may equally impede the smooth supply of munitions for the forces, raw materials for our factories or provisions for the civil population, impair the efficiency of a civil defence body such as the Auxiliary Fire Service, or deal fatal blows at the morale of the nation, upon which the sustenance of our war effort finally depends.

There is urgent need for searching scrutiny from above of almost every side of civil administration and leadership. Some, indeed, have already received attention from the Select Committee on National Expenditure, and the wide range of the admirable reports which that Committee has already issued suggests that such a further survey of civil administration and command might well come within its orbit. It may at least be hoped that the Government will speedily implement such an inquiry, whether through the Select Committee or some and other preferred means, and take the immediate and appropriate action on its findings. Only so can we ensure that parochialism, departmentalism and administrative incapacity no longer offer the barrier to our national effort which they have long offered in local government and to the development of regionalism, and which, if unchecked, they will assuredly offer to post-War reconstruction.

STATE PLANNING OF RESEARCH

The Contempt of Freedom:
the Russian Experiment and After. By M. Polanyi. Pp. ix+116. (London: Watts and Co., Ltd., 1940.) 5*s*. net.

IMPATIENCE at the delay in attaining the higher level of human welfare which science has made possible has led to a movement for the organization of research under State control and its more direct application to industrial and economic ends. Prof. Polanyi subjects this movement to a profound and penetrating criticism. He concludes that it would tend to lead to the loss of freedom of thought and freedom of expression of views contrary to authority and shows that this is, indeed, what happened in the U.S.S.R. with the vertical organization of research to State ends and under State control. The results of State planning of research are as disappointing as the results of the economic and social planning which he also discusses.

This book contains a message and a warning for scientific workers enamoured of planning. The first objective of planning should be the maintenance of freedom of thought and expression where it still exists, and its return where it has been lost. This freedom is absolutely essential for original research. It is also the first essential for human progress. People in authority, even in democratic countries, may resent the exercise of this freedom by those under them. It can easily be lost unless it is continually defended and fought for. We are not so many generations removed from the time when expression of views different from those held by the Church or the State was followed by persecution and even death. In most of Europe to-day the torch of liberty has been extinguished. Truth is being forcibly suppressed, and public opinion moulded for State purposes by open and hidden forms of propaganda, which prevail because those who know the truth are rendered dumb.

Even in democratic countries, there is a danger of the voice of reason being drowned in the flow of political propaganda, and the organization of science by the State may deprive scientific men of the full liberty of expression and freedom to criticize the policy of those in authority. The only authority scientific workers acknowledge is the truth. In these dark days through which civilization is passing, probably the most valuable service which men of science can give to humanity is the defence of freedom, described by Milton as "the liberty to know, to utter, to argue freely according to conscience which is above all liberties".

PHOTOSYNTHESIS BY PLANTS AND BY CHEMISTS

Photosynthesis
By Prof. E. C. C. Baly. Pp. vii+248. (London: Methuen and Co., Ltd., 1940.) 15*s*. net.

TWENTY years ago Prof. Baly first became interested in the debate whether formaldehyde could be photosynthesized artificially in a solution of carbon dioxide. Since then he has been continuously engaged in restating, retesting and reconsidering the problem. Now, in his retirement, he fights his battles over again within the covers of this book, recording successes which advance far beyond the first objective. Not only has formaldehyde been produced, but also glucose; a starch; the bases imidazole, pyridine and piperidine; coniine and two other alkaloids; α-amino-acids, including histidine; and a protein the molecular weight of which is given as 221·4. Very few of these substances have ever been photosynthesized in any laboratory other than that of Prof. Baly.

The path leading to these results has not been facile; on the contrary, the conditions of success have often proved stringent, and apparent successes, even though not illusory, have not always proved to be quite what they at first appeared. As an example the synthesis of mixed carbohydrates with the assistance of nickel carbonate may be mentioned. An independent attempt at repetition failed completely, to the emphatically expressed surprise of the author, who had believed the results to be reproducible and their confirmation a simple matter. It proved in the upshot to be far from such, and neither Prof. Baly nor anyone else has yet succeeded in repeating the results originally obtained in 1928. The margin between success and failure is believed to have been the chance use of a glass of abnormally low solubility which it has not been possible to get again.

With so much hanging upon so slender a thread, it would obviously be an impertinence for one who has not engaged in the actual experiments to comment on their technique and value. It is enough to record that, with the closure of the approach through nickel carbonate, recourse was had to the oxide, either suspended as a powder or supported on a kieselguhr base. The addition of thorium oxide in the ratio 1 ThO_2 to 24 NiO led to what Prof. Baly entitles "The Final Achievement". "When kieselguhr, which is completely coated with a tri-molecular layer of these oxides, is irradiated in presence of water, saturated with carbon dioxide, by daylight or the light of a tungsten filament lamp, there is photosynthesized a carbohydrate." This carbohydrate is not, however, a common one. After hydrolysis with sulphurous acid—but not before—it gave a Molisch reaction, and it passed slowly at room temperature and rapidly at 60° C. into a starch. The identification of the starch was carried out by hydrolysis with taka-diastase and boiling with Fehling's. This might be thought a little clumsy, since taka-diastase is not specific to starch nor Fehling's to glucose, or even to sugars. The only reference made to an iodine-blue test (a somewhat obscure one on p. 200) considers its negative result not surprising.

Prof. Baly is greatly impressed by the similarity between his nickel-catalysed photosynthesis and the natural chlorophyll-catalysed process in plants. Nickel oxide has a higher oxidation form in nickel sesquioxide, just as chlorophyll A has chlorophyll B. Both are green. Photosynthesis *in vitro* (1928 results) and *in vivo* both have a temperature optimum at about 30° C. and, by a fortunate selection of the physiological data, their Q_{10}'s have been made to appear the same. Both processes show a falling yield per unit quantity of light with rising light intensity; and the author believes that both may give rise to a starch without the free formation of any simpler substance. He is able to conclude "There is little doubt, therefore, that the mechanism of photosynthesis is the same in each."

The weight attached to the argument by analogy can only be described as crushing. Since nickel oxide requires thorium oxide to develop its activity, it is assumed that chlorophyll must need a similar inactive substance. The author is aware that some plants possess traces of boron in their leaves and will not grow normally in its complete absence. On this evidence he is prepared to believe "This function" of boron "would undoubtedly appear to be identical with that of thorium oxide in the case of nickel oxide."

On such analogies the author proposes a theory of natural photosynthesis which is in some respects remarkably explicit. It may be summarized by the equations:

(1) $C_{55}H_{72}O_5N_4\ MgCO_2H_2O + h\nu_1 = C_{55}H_{70}O_6N_4\ MgH_2O.CHOH$,

where $\nu_1 = 7{\cdot}1799 \times 10^{14}$;

(2) $C_{55}H_{70}O_6N_4\ MgH_2O.CHOH + h\nu_2 = C_{55}H_{70}O_6N_4\ MgH_2O + CHOH$,

where $\nu_2 = 4{\cdot}1615 \times 10^{14}$ and CHOH is activated formaldehyde;

(3) $C_{55}H_{70}O_6N_4\ MgH_2O + C_{40}H_{56} = C_{55}H_{72}O_5N_4Mg + C_{40}H_{56}O_2$;

and a fourth unformulated process in which xanthophyll is reduced back to carotin with liberation of free oxygen.

Referring to this mechanism, the author makes two statements: ". . . the mechanism of photosynthesis has been found . . ." (p. 210) and "No experimental proof of this mechanism of photosynthesis in the living plant can be adduced . . ." (p. 182). To any plant physiologist it must bristle with improbabilities. It is possible here to mention only a few at random. The transition from chlorophyll A to B is not a simple act of oxidation, and the location of the additional oxygen atom, now known to be in an aldehyde group, makes the process difficult to imagine. The necessity for light of two different wave-lengths rests upon very slender evidence; nor is any attempt made by the author to substantiate his assertion that the small leak of unwanted wave-lengths is sufficient to produce the photosynthesis observed in "monochromatic" lights. By the author's own computation a two-quantum process would require quite incredible energy efficiencies: observation uncertainly suggests a minimum requirement of 4 quanta. Although reduction of chlorophyll B hydrate by carotin is regarded as "the only possible mechanism of the third reaction of the photosynthetic cycle", there is as yet no evidence at all that the yellow pigments take any part in the process. The kinetic equations developed from the above are said to give a quantitative explanation of the relation between rate and controlling factors, including temperature, although the thermal reaction leading to the evolution of oxygen is not formulated. The meaning attached to "rate of photosynthesis" is not defined; but in the experiments of Warburg and Emerson which are used as tests, the rate measured was that of oxygen output.

After a careful reading, one may perhaps be forgiven for suggesting that this book could have been greatly improved by a more thorough elimination of inconsistencies and loose analogies, and by a deeper consideration of modern photosynthetic studies. W. O. JAMES.

THE CONTROL OF DISEASE

Man, Microbe and Malady
By Dr. John Drew. (Pelican Books.) Pp. 218. (Harmondsworth and New York: Penguin Books (Allen Lane), Ltd., 1940.) 6*d*. net.

The Conquest of Bacteria
from 606 to 693. By Dr. F. Sherwood Taylor. Pp. 144. (London: Martin Secker and Warburg, Ltd., 1940.) 6*s*. net.

(1) MR. H. G. WELLS remarked a little while ago that the only books worth buying to-day are the sixpenny editions. This tongue-in-cheek statement may have achieved little except a salutary effect upon Mr. Wells's publishers, but there can be no doubt that the cheapness and the increasing range of titles offered as 'paper-backs' is not only extending the numbers of the reading public but is also contributing very greatly to a more rapid dissemination of original thought and research among lay readers. In no case is the latter measure more desirable or necessary than in the field of science. This is significantly so in those practical and social implications which cannot fail to add to the more vigorous pursuit of health. For this reason Dr. Drew's book must be rated of the first importance. Its price does not run parallel with paucity of material nor with lack of care in presenting it. While it has been written primarily for the general reader, "Man, Microbe and Malady" would not make unprofitable reading for medical students or general practitioners.

A suitable introduction to enable the non-biologist to grasp the real nature of bacteria is followed by an account of their methods of infection and transmission, together with descriptions of the protective mechanisms, both natural and acquired, of the human body against bacterial attack. Some of the more common bacterial diseases are described in a further section, succeeded by chapters on the part played by insect and animal vectors in spreading disease. A concluding chapter on bacterial warfare minimizes the possibilities of its adoption to-day, while in an epilogue the author wisely addresses himself to those individuals who might develop phobias about certain diseases after reading a book of this nature.

The book would be valuable if only as a means of enlightening the general public as to the perniciousness of many patent medicines, and the imaginary complaints which they are designed to remedy such as night-starvation. Drew does not flinch from exposing the multifarious concoctions that are advertised so skilfully and spuriously as the infallible elixirs of life.

One section on diseases of the genital system is refreshingly frank and outspoken. In view of Mr. Malcolm MacDonald's recent utterance in the House of Commons that there are indications of increases in the number of new infections in all parts of the country, this is particularly opportune. Because of their extreme national importance, one or two of the statements need careful scrutiny. The author's dogmatic remark that 10 per cent of the population of Great Britain are syphilitic is open to question; the widest possible estimate would not place this figure above 4 per cent, while it is probably much lower. One shares all the author's commendable anxiety to convince British citizens of the terrible consequences of untreated venereal infections; but one cannot believe that more will be achieved by exaggerating the true position.

One point that may cause unnecessary alarm and misgiving to some of his readers lies in the author's ambiguous statements about the hereditary nature of syphilis. The direct reference to hereditary syphilis is unfortunate, especially as great care is taken later to describe its sometimes *congenital* origin. The bald remark that the taint of syphilis can be passed on to the third, and possibly even the fourth generation, might have been qualified by a paragraph on the methods of transmission in these cases and by a reminder that they occur with extremely low frequency.

The author's attitude towards prostitution, if acted upon, might be one of the most effective methods in checking the spread of the venereal diseases. In order to safeguard the general health of the nation he suggests that "we should take the common-sense view of prostitution" and then implies that we should establish brothels in Great Britain. The moral sanction invoked would be vigorously contested by our religious leaders, while Drew's citation of France as a country where the "logical attitude towards immorality" has been found satisfactory in controlling these diseases would need greater support from official figures than has hitherto been available.

A very small point: the present shortage of onions should do much to assuage the author's feelings about the allergic relationship between these greatly sought after comestibles and pregnancy.

(2) The use of drugs as therapeutic agents has been investigated for many years; but, apart from quinine, it seems only a short while since really fruitful results have been obtained. Ehrlich's discovery of salvarsan—so skilfully portrayed

in the film called "The Magic Bullet" which is now being shown in the provinces of Great Britain—together with the elaboration of Bayer 205 (against sleepy sickness) and emetine (against amœbic dysentery) were followed by the production of the remarkable drug prontosil, by Gerard Domagk and his co-workers at Elberfeld in 1932–35.

Since that time intensive research into the sulphanilamide compounds has culminated in the discovery of M. and B. 693 (which is as far as this book goes), a drug which is of tremendous significance in the treatment of certain streptococcal infections and which has already saved thousands of lives.

These outstanding advances in chemotherapy are the theme of this well-written book. It has been prepared for the layman; but, since it is the first to deal with these important matters in present-day medicine, it should secure many readers from the medical fraternity. For the latter, particularly, the book would have been even more valuable if Dr. Taylor had quoted statistics indicating the number of relapses after M. and B. 693 treatment for gonorrhœa. Conflicting reports tend to suggest that these relapses occur more often than was realized when this treatment was originally introduced.

T. H. HAWKINS.

A QUESTION OF TASTE IN PHYSICS

The Special Theory of Relativity
By Prof. Herbert Dingle. (Methuen's Monographs on Physical Subjects.) Pp. vii+94. (London: Methuen and Co., Ltd., 1940.) 3*s*. 6*d*. net.

THE scope of this book is indicated by the fact that it is based on lectures to honours physics students, and the treatment by the fact that it follows the lines of Prof. Dingle's recent contributions in NATURE. The interest provoked by the latter may justify the length of the present notice.

Dingle states the principle of relativity as, "There is no meaning in absolute motion". It might have been better to start with the more positive assertion that, when we speak of a velocity, we mean the relative velocity of two particles, and that the theory of relativity is concerned with the composition of such relative velocities. For Dingle seems to imply that his principle involves at the outset an advance on the ideas of classical mechanics. But that this is not necessarily so is shown by the fact that, if we let "c" tend to infinity in the formulæ of special relativity, we recover those of classical mechanics; this mathematical operation would not re-introduce "absolute motion" into a theory which attaches no meaning to it.

The same sort of *a posteriori* examination shows that the formulation of special relativity is essentially bound up with the introduction of this finite constant "c". This is in every development sooner or later identified with the velocity of light. In one like Dingle's based on "relations first discovered in the world of experience" we expect, therefore, to find that observational results on the propagation of light form the real starting-point. This expectation is in fact fulfilled in his book, but, instead of immediately making what has come to be the traditional use of the results, he first introduces a postulate about length, and later reverts to the traditional method to derive the Lorentz transformation (though remarking that it could have been derived from results already stated). Moreover, his derivation is defective, since it applies only to events on a light-track (equation 19).

Thus the author's procedure seems rather to obscure than to clarify this crucial part of the subject. The difficulties are traceable to two reasons: his desire to treat the measurement of length as more rudimentary than that of time, and his desire to avoid the introduction of more than one observer (both of which he has expounded in his articles in NATURE). There is no fundamental objection to the principles underlying these desires. However, it seems to the reviewer that Dingle does not rigorously follow out their implications, but, in some respects, pays mere lip-service to them while implicitly drawing upon assumptions not actually stated.

This is not the occasion to attempt a statement of a set of initial propositions for special relativity. But one may point out that, keeping to the class of ideas dealt with by Dingle, we must assume an observer to be equipped with some sort of "measuring-rod" and some sort of "clock". Now these must be *graduated*, and this introduces a problem not fully considered by Dingle as an essential part of the whole argument. He apparently supposes that the observer can regard a rigid measuring-rod as given, and can assume that the velocity of light, *in văcuo*, is constant. But these assumptions, taken together, permit a unique graduation of his clock. Conversely, the observer could regard a "uniformly-going" clock as given and, assuming the velocity of light to be constant, could derive a unique graduation of his measuring-rods. The choice between the two procedures seems to be not one of logical necessity; what is essential is that this matter of graduation should be given its proper place.

Passing to the second point, Dingle prefers to state results with reference to a single observer using various co-ordinate systems, rather than with reference to various observers. To some extent this is a question of convenience of description of the results. But in order to give a complete development of the subject without postulating more than one observer demands a deeper investigation than that given. For example, Dingle proposes (p. 23) to define length by a formula $l\sqrt{(1-v^2/c^2)}$, where l is what is usually called "proper length"; the question is, Who measures l? It is not sufficient to say that it is measured by the single observer who afterwards sets the body concerned in motion with velocity v, unless we add some postulates about accelerated motion and thereby transgress the usual scope of special relativity.

If Dingle is unprepared to base his revised formulation of the theory on an adequate set of postulates, it is hard to see what quarrel he has with current formulations. The answer to his objections would seem to be completely given by Prof. Campbell's letter in Nature (March 16, 1940) with, perhaps, added emphasis on the assumption that each observer graduates his scales and clocks in the above-mentioned manner, and that he can read the graduations used by other observers.

Beginners may fail to get a clear understanding of the theory from this book, though they are bound to find it stimulating. It is, however, assured of careful study by those having a special interest in this field. The reviewer wonders if they will share his conclusion—briefly this: All that special relativity claims to give is a better approximation than classical theory in dealing with some phenomena; it is admittedly inadequate in certain respects. So, leaving aside deeper questions of the nature of physical law, it is clear that we can scarcely have a *rigorous* deduction of special relativity from experimentally verifiable postulates. Any development of the theory must involve a tentative element to be judged on grounds of plausibility rather than rigour. Hence the choice of a formulation of the theory (as distinct from its application) is to a considerable extent a question of taste. Doubtless Prof. Dingle will not find himself alone in his particular taste in these matters.

W. H. McCrea.

EXACT STUDIES OF ORGANIC REACTIONS

Physical Organic Chemistry:
Reaction Rates, Equilibria and Mechanisms. By Prof. Louis P. Hammett. (International Chemical Series.) Pp. x + 404. (New York and London: McGraw-Hill Book Co., Inc., 1940.) *26s.*

In the preface to this volume Prof. Hammett truly says: "It is one of the commonest occurrences in the development of science that the necessary subdivision of the subject leads to a temporary neglect of phenomena lying on the borders between specialised fields." Fortunately, both in Great Britain and in the United States this extreme specialization has not prevented chemists from recognizing that fundamental physical theories are quite as applicable to problems in organic chemistry as they are to studies of the simpler inorganic compounds. Chemical studies of reaction mechanisms can have little value unless they are developed from basic theories of molecular structure and statistical thermodynamics. These have been summarized logically in the first third of this volume and thereafter have been applied to the quantitative consideration of the majority of the well-known reactions of organic chemistry.

The majority of the reaction mechanisms discussed by Prof. Hammett were originally proposed by Lapworth, Robinson, Ingold and others in Great Britain, and it is evident to a British reviewer that many of the earlier suggestions were not, for some years, fully comprehended in America. Undoubtedly this delay in the dissemination of scientific theories has been due in great part to the plethora of ephemeral descriptive terminologies. To-day we need no groping qualitative descriptions, for the theoretical electronic basis of organic chemistry is now well established, and, as this book shows, can be presented in a readable, easily comprehensible, form.

Since an organic chemist has to concern himself with reactions occurring in solvents of all types it is necessary to generalize physical theories. Hence, as a unifying conception, the Lowry-Brønsted theory of acidity and basicity has been given its due place of predominance, and its wide quantitative applicability to reactions involving ionic substitution, acid and base catalysis, and molecular rearrangement has been shown. The 'transition state' conception, too, has been found to be invaluable in the discussion of the mechanism of complex organic reactions, and organic chemists will note with pleasure that the 'transition state' is frequently considered to be an ionized complex for which a definite graphic formula can be written. Among the more controversial of these graphic formulations are the postulation of a cyclic structure,  as an intermediate phase in the *trans*bromination of olefines, and the suggestion that the hydride anion, H^-, is a separable entity in the Cannizaro reaction of aldehydes. Suggestions such as these have been given strong logical support, and may be quoted as typifying the extent to which the author has been prepared to give prominence to his own considerable contributions to the development of organic chemistry. As a whole, "Physical Organic Chemistry" is both a valuable record of the present state of development of theoretical organic chemistry, and also a stimulating source of inspiration for future research work.

W. A. WATERS

HUMANISM AND LIFE

Our Human Truths
By the late F. C. S. Schiller. Pp. x + 371. (New York: Columbia University Press; London: Oxford University Press, 1939.) 15*s*. 6*d*. net.

THE late F. C. S. Schiller was one of the small group of Oxford tutors who some forty years ago or more won for a pragmatic philosophy a place in that University, and for a great part of his life he was among the foremost exponents of humanism. He was perhaps unique among philosophers in introducing into his work a strong seasoning of a somewhat Puckish humour, and his writings are illuminated from time to time by flashes of a mordant wit. In this volume are reprinted a number of pieces of philosophical and sometimes also of topical interest which were the recreations of the last years of his life, when illness enforced retirement from more active academic engagements. They have for the most part already appeared in philosophical, psychological or others of the periodical Press.

In these essays, classified under the headings of philosophy, literary criticism, philosophy in practice, political philosophy and logic, the practical bent of Schiller's mind is plainly discernible. For him philosophy—an empirical philosophy—was essentially and emphatically a way of life. As he argues forcibly in, for example, the two essays "Burning Questions" and "Must Philosophy be Dull ?" it was in the examination of such living problems as the nature of the self, which he regarded as the crux bequeathed by earlier philosophies from Descartes onward, that a future alone lay for these studies. So far was he averse from the logomachies of *a priori* schools, that he regarded their topics of discussion not only as arid, but also as fatal to the survival of philosophy at all.

In the section devoted to literary criticism, Schiller was particularly happy in his study "Goethe and the Faustian Way of Salvation", in which the exposition of the poet as philosopher and man of action combined afforded scope for his powers of critical and psychological analysis. It is, however, in its approach to the standing of science and scientific thought that his empirical philosophy assumes its most characteristic pragmatic attitude. Pure science, disinterested research, he regards as a late specialization in development, but science in its origins and throughout its history has developed from time to time in response to man's needs, material, intellectual and spiritual. Hence the principles and conclusions of science are not fixed and immutable but hypotheses of which the test value is not validity; but how far they are found to work, and to be scrapped and reformulated if necessary as experience and knowledge grow.

Schiller was strongly attracted by current questions of the social and international situation. It is interesting to see with how open and disinterested a mind he examined conflicting political systems in the light of his philosophy. Had he lived longer, matters upon which he necessarily suspended judgment in the totalitarian systems would probably have ceased to be open questions, though democracy on its side would not yet have purged its failures. On "The Crumbling British Empire" Schiller was early in seeing the full implications of the Statute of Westminster, which had been realized by few outside official circles at the time he wrote. Yet he recognizes that there are no precedents for the British Empire and suggests that if by some divine grace or lucky chance it can hold together by dint of mere sentiment, it may give a valuable lead to, and serve as a model for, the rest of the world. One question raised by him, in which he saw a possibility of dispute or at least of friction, namely, a declaration of war by the mother country, has been answered—happily.

THE POTATO AS FOOD

"THE United Kingdom has just had the largest crop of potatoes for many years, and unless the consumption is increased beyond the present level there will be a large surplus at the end of the season. . . . Potatoes are one of the best foods grown, for they are both energy-producing and protective." (*The Times*, January 15, 1941, quoting the Ministry of Food.)

One is perhaps prompted to query whether this forecasts an increased surplus over this year, when the tonnage of potatoes which the public will not be able to consume reaches almost astronomical figures. Moreover, what does this somewhat loose expression "energy-producing and protective" mean ? It therefore seems apposite to consider whether the discussion on the potato as food, which took place a few weeks ago, helps to assess the value of the potato ; the meeting was held under the auspices of the Nutrition Panel of the Food Group of the Society of Chemical Industry, and three papers were presented and discussed, concerned respectively with the biology (Dr. Redcliffe Salaman), the chemical constitution (Dr. L. H. Lampitt and Mr. N. Goldenberg), and the nutrition value (Dr. Harriette Chick) of the potato. All authors agreed on the importance of the potato as an article of diet ; but all three papers also indicated the lack of scientific knowledge and the desirability of well-planned and comprehensive experiments. This point was stressed particularly by Dr. Salaman and by Dr. Lampitt.

Dr. Salaman has made a detailed study of the history of the potato, and those who have read his various publications on this matter must recognize how much science owes to him for unravelling a very tangled skein. A proper understanding is essential if progress is to be made.

It is possible that the potato breeder is at the end of his tether in respect of improving the varieties from the available material, and one has heard with great satisfaction of the collection of potatoes at Cambridge made during the years immediately preceding the War from parts of South America, including the High Andes. One hopes that these experiments will not suffer the fate of so many Government schemes of research and be jettisoned on the score of expense. The importance to the potato breeder of new varieties, the introduction of 'new blood', cannot be over-estimated. If it is agreed that more potatoes still should be grown, the importance of virus-free seed has been amply demonstrated. Possibly the solution of the problem is not quite so simple as expounded by Dr. Salaman ; in fact, the Board of Agriculture appears (from one of the speakers in the subsequent discussion) to be somewhat sceptical of the virus-free theory. However, as a working hypothesis the advantage of stock not affected by the potato virus cannot be denied.

Moreover, it has already been pointed out that, with attention to peeling and 'eyeing', an increase of more than 33 per cent in potatoes 'ready-to-eat' is possible in Great Britain without increasing the acreage of land under potato crop ("The Nation's Larder"). Whilst it is recognized that the careful peeling necessary to achieve this increase is probably outside the scope of the housewife, an increase of 20 per cent should be capable of realization. Obviously, the greatest claim that can be made for potatoes is that they are home grown, and that valuable shipping space might be released if the amount of grain to be brought from overseas could be reduced. The $\frac{3}{4}$ lb. *per diem* for each head of the population would not be excessive. There are many countries where this figure is exceeded. An example is Germany, where for years previous to the outbreak of the War the use of potatoes was enforced as a diluent for wheat flour. It is, in fact, to the potato that Governments lead the nations when measures of economy are necessary.

This makes it all the more difficult to understand the paucity of basic knowledge on the chemistry of the potato. The variability of the tuber and the number of factors involved, make it essential that all experiments be planned on a large scale so that a statistical study can be effectively made. Some years ago an extensive investigation of certain factors was undertaken by the Rothamsted Experimental Station, and for two or three years previous to 1929.

It is a notable fact that the consumption of potatoes declines as the so-called 'standard of living' rises. Dr. Salaman thinks, too, that the craze of 'slimness in women' is a contributory factor, but our observations would lead us to suggest that this 'fear of the potato' is not confined to women ; many of those of the male sex who bow down to the god of physical fitness shun the potato.

The Potato Marketing Board had a most comprehensive study of the 'blackening' of potatoes in progress ; this investigation was abandoned, however, presumably as a measure of economy, a decision of a Government department that all should deplore, for in certain seasons this 'blackening' effect causes great loss to the nation.

The survey of the literature (*J. Soc. Chem. Ind.*, 59, 45, 748) with its reference to some 250 papers, seems to prove that very few of the statements that have been made have been definitely corroborated. It was pointed out that many of the observations recorded are either fragmentary or directed towards some isolated problem. The non-static character of the potato itself is to some extent responsible for the lack of uniformity of the results obtained. Variety, age and condition of growth are all major factors in the composition of the potato, and when to these are added the fact that the potato is not homogeneous, and that the greater number of workers have failed to state whether their analyses were conducted on peeled or unpeeled tubers, the chaotic condition of the data is to be understood. Lack of details of the method used in preparing a sample for examination is one of the most common failings in the description of much of the work on 'natural' products in the food world, and it is a point of interest that at meetings of the nature of the one in question, attempts to summarize present knowledge demonstrate the great importance of such elementary precautions.

Meetings of this nature are of importance, if only that in these times they make it possible for the 'fringe' scientific worker to evaluate the dicta, or even the advertisements of the Minister of Food.

Dr. Chick quoted figures which give some information relative to the 'energy-producing' value of the potato. 100 gm. of potatoes baked in the skins is equivalent to 113 calories, whilst 100 gm. of white bread is equivalent to 260 calories; in other words, the potato as prepared in this manner has a caloric value less than half that of the same weight of bread. Of the mineral elements, the importance of which in nutrition cannot be denied, potatoes are less effective than bread.

As 'protective' food, an important effect of potatoes is to provide or supplement the B-vitamins. Vitamin B_1 (aneurin) is probably present to an extent of about one quarter of that of wholemeal bread, for as Dr. Chick stated, the aneurin contents of potatoes and of wholemeal bread are approximately equal when the dry weights of the foods are taken into account. Unfortunately, little reliance can be placed on the scattered results in the literature concerning the other B-vitamins.

The importance of the potato as an antiscorbutic has also to be considered. The fact that scurvy has appeared in countries largely dependent on the potato for food, when the crop has failed, is a significant fact, and evidence was forthcoming in the discussion of the papers that the tuber is a necessary source of ascorbutic acid. If, however, full advantage is to be taken of the vitamin C content of potatoes, then the water in which the tubers are boiled should be consumed, for there is considerable loss of ascorbutic acid by diffusion into the water. Here the nutritionist and the gourmet are in agreement, for M. André Simon, who was chairman of the meeting, remarked on the value of the potato water in the preparation of soups and sauces.

DIET IN RELATION TO DENTAL CARIES*

BY PROF. E. V. MCCOLLUM,

JOHN HOPKINS UNIVERSITY

THE carious lesion in a tooth is caused by acid decomposition of the enamel, and afterwards the dentine, associated with proteolytic destruction of the organic substance of the tooth. Caries of the teeth is restricted to man and other animals which eat liberally of carbohydrate-containing foods. Carnivorous man and animals do not suffer from this disease. Dental caries does not attack the surfaces of teeth indiscriminately, but occurs only at such sites as favour the lodgment of food residues, as in pits or fissures, or on surfaces of the enamel which harbour mucinous plaques. In such sites acid is formed by fermentation of carbohydrate by micro-organisms, and is protected against being washed away by saliva or by neutralization by salivary alkalinity.

Throughout the Americas and Europe, and in most other temperate or torrid parts of the world, almost everyone eats liberally of carbohydrates, so the pabulum for feeding micro-organisms of every kind associated with fermentations is present in abundance at times in every mouth. Yet there is a great variation in the susceptibility of different people to dental caries. Numerous investigations have been devoted to attempts to discover why this great variation exists. Bunting and his associates, and Fosdick and his associates, have been foremost in studies of the microbiology of the oral cavity and its relation to caries of the teeth. A number of distinguished investigators have studied various aspects of the relation of the diet to susceptibility to this almost universal human affliction. I shall limit what I have to say to the nutritional aspects of this problem.

---

* Substance of a paper read on September 18 at the Bicentennial Conference, University of Pennsylvania.

TOOTH STRUCTURE IN RELATION TO DENTAL CARIES

There is almost general agreement that potentially carious areas can be detected by a careful examination of the surfaces of the teeth. Dr. Thaddeus Hyatt, during his long tenure as chief of the dental clinic of the Home Office of the Metropolitan Life Insurance Company, directed his staff to explore the enamel surfaces thoroughly with a fine tine and when pits were found these were drilled and filled and the surfaces polished, thus eradicating potential food traps, or areas where stagnation and acid formation was likely to produce later carious cavities. This system of caries prevention is known as prophylactic odontotomy, and has been found effective by others as a means of preventing the disease. It is fully established, therefore, that developmental defects in the enamel may predispose teeth to decay.

FAULTY NUTRITION AND DEFECTIVE TOOTH STRUCTURE

Experimental work with animals has shown clearly several ways in which dietary deficiencies during the period of tooth development can impair tooth structure. One of these is vitamin A deficiency. In deficiency of this nutrient the epithelia, no matter how they are specialized, as in mucous membranes, glandular secreting structures, and skin, suffer changes in structure and in loss of physiological function. Keratinization and desquamation of epithelia find their counterpart in the enamel-forming organ of the developing tooth, in changes in structure and partial or complete loss of function. The enamel-forming organ is of epithelial origin, being derived from embryonic gum tissue. Each cell of this organ secretes calcium, phosphate, fluoride, magnesium, and carbonate ions in such a way as to cause them to combine and deposit in the form of tenuous enamel prisms. These prisms form a mosaic, which, in the normal tooth, is of great perfection. When, owing to vitamin A deficiency, the enamel-forming cells are injured, prisms which are less dense than normal, or incomplete as to length, and imperfectly fitted together, form defective enamel. In the milder grades of this type there are pits in the enamel. In more severe grades of injury, the surface of the enamel of the greater part of the whole of the tooth may be rough, the enamel thin and deficient in hardness. This is the hypoplastic tooth.

A second situation which may cause defective enamelling of the teeth is that seen in the disturbance of calcium and phosphate metabolism seen in the ricketic state. When the diet is complete as regards vitamin A and all other factors which are concerned with the promotion of healthy development, except vitamin D, the enamel-forming organ may be normal in every way, but be unable to withdraw from the blood the necessary structural materials for the formation of normal enamel. In rickets the concentration of phosphate ions in the blood falls below normal, and this interferes with the formation of sound enamel because the solution from which the cells derive their substances is too dilute.

Defects of enamel having their origin in disturbance of calcium and phosphorus metabolism have been most thoroughly studied by Lady Mellanby. She drew the conclusion from her observations that deficiency of vitamin D is of primary significance in predisposing teeth to caries susceptibility. The phosphate ion of the blood is maintained at normal concentration by the provision of this vitamin and, in addition to preventing defective bone growth, likewise has an important role in safeguarding the developing teeth against defects of structure. Lady Mellanby reported extensive experiments with children in Sheffield and Birmingham, all of whom were fed alike. To groups of these she gave generous prophylactic doses of vitamin D over a considerable period, and found that the incidence of dental caries was much lower in these groups than in the controls not receiving the vitamin. She expressed the belief that a diet highly favourable to normal calcification of bones and teeth could in considerable measure lessen the incidence of tooth decay.

McBeath, of New York, has carried out experimental studies with large numbers of school children over a period of several years, along the lines laid down by Lady Mellanby. He finds that there is a seasonal incidence of dental caries, the highest incidence of new cavities occurring in late winter and spring, and the lowest in summer and autumn. These observations he correlates with the amount of ultra-violet light which the children receive at different seasons. He further found that when liberal daily doses of vitamin D were given children during the colder months, the seasonal curve of incidence is flattened out, the incidence during the months of low sunshine being closely similar to that of summer and autumn. This type of experiment places vitamin D, for which suitable doses of ultra-violet light is the equivalent, in the position of playing a significant part in influencing the susceptibility of the individual to dental caries.

It is difficult to see how vitamin D can protect the teeth against decay merely by maintaining the body in a state favourable to calcification. Caries of the teeth occurs as the result of highly localized processes. In an area of stagnating food residues, acid is formed and protected against removal or neutralization, and is able to act more or less continuously in dissolving enamel. There appears to be no possible mechanism for resistance to acid erosion by enamel other than its density, which can be of but minor importance since the most perfect enamel is dissolved by acid when the pH reaches about 4·6, and the quality of enamel is not modified by any known agency after it is once laid down. If it is confirmed that sufficient ultra-violet light or of vitamin D favourably influences the body in its power to resist dental caries, it would seem that we must seek for an explanation in some effect upon the immunological mechanisms, which are of a nature to suppress the growth or functions of the microbial flora ordinarily associated with acid formation in the mouth. This might be exercised through the saliva or mucus, or other agency possessed by the epithelia. There do not appear to have been any studies recorded to test whether ultra-violet rays or vitamin D administration modify the oral flora.

That an immunity to dental caries may be artificially induced is suggested by the success of Bunting and Jay in preparing a vaccine from cultures of *Lactobacillus acidophilus* which they isolated from carious cavities. Upon intradermal innoculation of caries-susceptible persons there was a cutaneous reaction in nearly all cases, and when the test was applied to a series of caries-immune subjects, the skin reaction was almost always negative. There are in the population a considerable number of people who apparently eat as wide a variety as do most of us, and certainly eat freely of some form of carbohydrate, yet are caries-immune or nearly so. Some are immune to caries of the teeth during a period of years and then become susceptible. There seems much reason to attribute such immunity to systemic condition of some kind, and the most plausible explanation would seem to be an immunological one—the offending organisms find the mouth environment unfavourable because of the presence of something detrimental, and this something seems to be the product of the living tissues or glands accessory to the mouth.

EFFECTS OF EATING SUGAR ON CARIES INCIDENCE

The eating of sugar and sweets has long been popularly believed to cause the teeth to decay. This view is supported by the observations of Bunting and his co-workers, who, by means of dietary control, reduced the incidence of dental caries in an orphanage to a very low level. Upon permitting a group of children, whose mouths were free or nearly so of *Lactobacillus acidophilus*, and who were classed as caries-immunes, to eat about three pounds of candy per week, they found that they soon became caries-susceptible, and that the oral flora returned to the caries-producing type.

It is difficult to explain why eating sugar should be more likely to induce dental caries than cooked starch. Sugar is so easily soluble that it tends to be swallowed promptly as fresh quantities of saliva are secreted. Cooked starch, on the other hand, is pasty and is easily lodged in pits and fissures. Mixed with saliva and acid-forming organisms, starch would continuously undergo diastatic conversion into maltose, a fermentable sugar, thus furnishing an uninterrupted supply of nutriment for acid formation. Yet it is concluded by Bunting that this is not the case. Human experience confirms the findings of Bunting that people may eat freely of starchy foods and yet remain free from dental caries, or nearly so. An example are the people of the Island of Tristan da Cuhna, who consume potatoes as a staple food. The primitive Pacific Islanders, before the era of exploration, ate largely of starchy foods, yet they were almost free from dental caries. Sugar, therefore, seems on the basis of scientific observations now available, to be far more of a menace to the health of the teeth than are the starchy foods.

A dietary study of outstanding interest in relation to the caries problem was reported in 1926 and 1928 by Bodd and Drain, of the University of Iowa. They made repeated routine examinations of the teeth of the patients in the pediatric clinic over a period of some years, and encountered many teeth which had large cavities, which, ordinarily, would have an area of softened dentine surrounding the zone of destruction, but in these patients were found to have uncommonly dense and hard dentine walling off the cavities and arresting the progress of the carious processes. These cases of arrested caries, in which a secondary deposit of dentine had occurred, which formed an effective barrier against further invasion of the tooth, were found to be without exception diabetic patients. The arrest of dental caries appeared to have occurred as the result of their having been restricted to the low-carbohydrate high-fat type of diet now generally used by diabetic patients. This type of diet does not seem to have been further studied as a means of controlling dental caries, and is worthy of most careful consideration. If replacement of a considerable fraction of the carbohydrate moiety in our daily diets by fat will protect the population in great measure against dental caries, the fact should be made known, and such a diet recommended for non-diabetics.

But human experience appears to afford fairly numerous examples of peoples who in great measure escaped the ravages of dental caries, who did not eat low-carbohydrate high-fat diets. Chinese students in America appear to have a lower incidence of caries of the teeth than do persons of similar ages who have grown up in America. I have been repeatedly told by Chinese students that they experienced markedly increased incidence of tooth decay after spending a few years in the United States. The great majority of Chinese people have from very early times eaten freely of starch-rich vegetable foods. They eat various vegetable foods which have a detergent action on the teeth, which may be a factor of considerable importance in preventing stagnation areas.

Experimental studies on the effects of deficiency of ascorbic acid on the teeth indicate that the dentine-forming organ, the odontoblastic membrane, is peculiarly susceptible to injury in this deficiency state. The odontoblastic membrane lines the pulp cavity, and from its cells filaments (Tomes fibrils) permeate the dentinal tubules, which permeate the dentine to the base of the enamel. It seems certain that it is through the functioning of these fibrils that secondary dentine can be laid down near the outer border of dentine whenever irritation arises. This is a peculiar repair process, which, when the state of nutrition is near the optimum for calcification, can be called into being so as to arrest caries by a walling-off process. In this respect the perfection of function of the odontoblasts, which is influenced profoundly by the ascorbic acid supply, becomes an agency in the prevention of the extension of dental caries, but not of its incidence.

The fact which has been thoroughly established by the work of Bunting with institutional groups of children, all of whom were provided with the same food, is that there are individuals in whose mouths *Lactobacillus acidophilus* grows profusely, and forms the principal flora, whereas the mouths of other individuals contain principally organisms of other types. This would seem to demonstrate that the character of the oral flora depends greatly on conditions other than the character of the food eaten day by day, especially when a mixed diet, affording a fairly wide variety, is eaten. The most plausible explanation for the observed facts would seem to be found in the humoral defence mechanisms of the mucous surfaces, the mucous secretions of the saliva. We have one outstanding example of the relation between the state of nutrition and the character of the oral flora. At one time it seemed that Chittenden and associates at Yale University, and also Goldberger, in Washington, were dealing with the same state of malnutrition in their experimental dogs, both believing that the condition produced by their different faulty diets was the analogue of human pellagra. At Yale the dogs were cured by the administration of butter or boiled carrots, both of which are sources of vitamin A. At Washington, what appeared to be the same disease could not be cured by butter or carrots, but responded well to yeast administration, which did the dogs no good. In 1937 Smith and his co-workers at Duke University repeated both experiments and found that in the one case the dogs were in a severe state of vitamin A deficiency, and in the other of nicotinic acid deficiency. In both cases the earlier experimenters had depended greatly on the mouth condition for making their diagnosis. The oral flora in both groups of animals was of the fuso-spirochætal type seen in Vincent's angina. This is an abnormal and pathological mouth flora, and overgrows the oral cavity when the tissues are debilitated. It appeared in the dogs as the result of two quite distinct types of malnutritional deficiency states. In these two conditions the overgrowth of the mouth by a pathological flora would seem to be best explained on the basis of a lack of some humoral factor or factors which the normal mouth contains, and which serves to suppress the growth of certain abnormal types of micro-organisms. Perhaps the decided differences in the oral cultures found in many individuals may be accounted for on the same basis, namely, the failure of the oral structures to produce some humoral factor of immunological significance.

The recorded experimental data seem to warrant the acceptance of the following conclusions :

If the nutrition of the individual is optimal during the development period of the teeth, their structure will be safeguarded, and freedom from structural defects such as pits, fissures, hypoplastic enamel, may be expected. It would seem that dense, thick, hard enamel must afford some degree of protection against dental caries.

A state of optimum nutrition appears to afford marked protection against dental caries. It seems certain that such protection is in considerable measure due to some property of the mucous secretions or of the saliva or both, which tends to suppress the growth or functions of micro-organisms whose presence in large numbers would be inimical to the health of the teeth.

Subsistence throughout life on a strictly carnivorous diet will prevent dental caries. This would be impractical in most parts of the world, and if practicable, would be less satisfying than is a mixed diet. The presence of considerable carbohydrate in the diet is necessary for the development of carious teeth. There seems to be good evidence in support of the view that the regular consumption of a diet in which all the essential nutrients are present in adequate amounts, and in which the ratio of fatty acids to total carbohydrates (including the sugar which may arise from protein and glycerol) is not less than 1·5 : 1, prevents dental caries. This is equivalent to saying that a diet suitable for the diabetic is so constituted as to afford protection against dental caries, and even makes possible the arrest of the carious process in open cavities. This protective action of excessive fat in the diet may possibly be due to greasing the tooth surface and the cavity surface, thus waterproofing it and preventing access of water-soluble acids (for example, lactic acid) to the enamel surface.

There seems to be good evidence that the elimination of sugar from the diet, and the provision of carbohydrate in the form of starch, affords a less favourable oral medium for the development of acid-forming organisms, and so protects the teeth against acid decomposition.

It appears probable that the provision of an abundance of vitamin D, either taken directly, or derived from the action of ultra-violet rays on the skin, exerts a favourable action on the immunological mechanisms in the oral secretions or on the epithelia of the mouth, and makes for preventing the growth of excessive numbers of acid-forming organisms.

The dentist can supplement the protection against dental caries which right eating can give, by early eradication of potential sites of decay.

The food should always supply certain things which require vigorous chewing, since teeth which are not exercised do not retain optimum health. Every meal should end with some food such as raw fruit or raw vegetable, which requires thorough mastication, both because of the exercise afforded the teeth, and for the detergent effect of chewing foods which do not have a tendency to adhere to the enamel surface.

EVOLUTION OF DEVELOPMENTAL SYSTEMS

BY DR. C. H. WADDINGTON,

DEPARTMENT OF ZOOLOGY AND STRANGEWAYS LABORATORY, CAMBRIDGE

THE theory of evolution is still the essential thread which connects together the numerous and diverse branches of biology. It has been clear at least since von Baer's day that a theory of evolution requires, as a fundamental part of it, some theory of development. Evolution is concerned with changes in animals, and it is impossible profitably to discuss changes in a system unless one has some picture of what the system is like. Since every aspect of an animal is a product of development, or rather is a temporary phase of a continuous process of development, a model of the nature of animal organization can only be given in developmental terms.

In recent times Goldschmidt has been the most prominent biologist who has attempted to describe biological organization in terms which are at once developmental and not too far removed from the genetical concepts employed by students of evolution. His great contribution to the topic was made by the publication in 1927 of his "Physiologische Theorie der Vererbung[1]". He pointed out that the development of an animal consists of a large number of correlated reactions proceeding at definite relative velocities; and he suggested that genes act by altering the rates of one or more of the reactions. This fruitful idea was successful in directing the attention of many geneticists to developmental problems, and has been the stimulus to much valuable work. It in no way diminishes the historical importance of Goldschmidt's theory to point out, after this lapse of time, that it is actually no more than the statement of the general notion of materialism in a four-dimensional world. So long as one considers development in material terms, there are only two things a gene could do: alter the velocity of a reaction (which includes arresting it completely), or initiate a new reaction; and the second of these can always be looked on as a secondary consequence of an alteration in the rate of some earlier reaction.

Before the theory can give us any specific picture of the kind of thing a developing animal is, it must be elaborated and restricted in such a way as to give it some concrete consequences. Goldschmidt attempted to do this by specifying a particular mechanism for the alterations in rate, which he suggested were caused by alterations in the quantity of gene material, which was thought of as acting in an enzyme-like way. Interesting as this suggestion is, it is not quite to the point so far as evolution is concerned. What evolutionary theory requires is not so much a hypothesis of the ultimate physico-chemical mechanisms of development, but rather a picture of the possible kinds of interactions between developmental processes ; it needs some framework of concepts in which it can discuss such questions as whether there is any difference in kind between specific and varietal differences.

I have recently[2] made some suggestions for an elaboration of Goldschmidt's hypothesis, which, it is hoped, will leave it general enough to apply to most, or all, developing organisms, but not so general that it applies equally well to the whole material universe. The most important of these suggestions can be summarized as follows :

(1) The course of a developmental reaction is the resultant of a large number of mutually interacting influences. If one plots a developmental process against time, one must regard the line as occupying a position of equilibrium, determined by a number of processes which tend to push it upwards and a number which tend to push it downwards. This notion might seem to be merely our old friend dialectical materialism rearing its head out of the shifting seas of metaphysical controversy. But it is more than that ; it follows directly from the experimental data concerning the effects of modifying genes, and of the general genetic background. It also issues in the following generalization from experience.

(2) In a normal animal, there are only a certain finite number of possible resultants of the interacting developmental processes. The final products of development, the adult tissues, do not, it seems, vary continuously from one type to another, but fall into a comparatively few tolerably sharply defined kinds. This implies that during development there is a succession of 'branching points', at each of which the course of development can move into one or other of a few alternative paths.

(3) One of the difficulties of an embryological theory has been to find a characteristic of a tissue which is causally connected with its future development. The classical concept of a potency is unsatisfactory because it is non-causal ; it merely allows one to describe whether or not a tissue does sometimes develop in a certain way. One can discover a characteristic of the required kind during a 'branch point'. At that time a tissue is in a state of indeterminacy between alternatives. This state, which I have called competence, is open to experimental investigation. It has the character of a readiness to react to certain stimuli (evocators), which may be applied either externally or, probably, from inside the cell. The future character of development depends directly on whether or or not such a reaction occurs.

(4) The definiteness of the alternative modes of development is a product of natural selection, and characterizes animals in the state of Nature. It is lost, or partially obscured, in most mutant forms.

(5) Other genes may cause particular regions of the body to enter upon a type of development which should characterize some other part. A clear example is the gene Aristopedia in Drosophila, which causes the arista (terminal section of the antenna) to develop in a leg-like manner.

Some, at any rate, of these points are adumbrated in Goldschmidt's writings ; but they have not been clearly realized by him. In his recent Silliman lectures[3] he is still concerned to show that time is the one and only essence of the matter. For example, he discusses the case of Aristopedia, and quotes his student Braun that the imaginal bud of the Aristopedia antenna becomes determined to develop into a leg at the same time as the leg buds are determined ; but he draws the completely unjustified conclusion that it is determined as a leg simply because of this temporal simultaneity. One might as well argue that because the neural plate and the epidermis of an amphibian become determined at the same time they must be determined to develop in the same way.

Goldschmidt's book is one of the most important of recent contributions to the theory of evolution. A very valuable feature of it is his masterly analysis of geographical variation, a subject in which his own researches have been of supreme importance. He presents considerable evidence that animals in Nature fall into groups between which there are 'unbridgeable gaps'. The groups may be small relict species or relatively enormous assemblages of intergrading forms. Their taxonomic treatment will be a matter of convenience ; but whether they are lumped as one species, or split up into a series of types each dignified with a specific name, is of minor importance in comparison with the essential fact of the existence of discontinuities between one set of intergrading types and the next. Evolutionary change within the group Goldschmidt names micro-evolution, while the arising of a new group separated from the old by a discontinuity, is macro-evolution.

A somewhat similar distinction has recently been made in the botanical field by Willis[4]. He suggests that the large groups arise by the working of "some definite law which we do not yet comprehend", and that then "evolution goes on in what one may call the downward direction from family to variety". Goldschmidt's view is somewhat similar in that he supposes that the evolution within the group merely brings about an increase in variability without producing any progressive evolutionary changes; but, unlike Willis, he allows that this micro-evolution is controlled by natural selection. His main criticism is directed, not at the theory of selection, but at the idea that macro-evolutionary change is dependent on genes. He is "firmly convinced that, except in micro-evolution, the facts already available to-day force us to drop completely from evolutionary thought the idea of so-called gene mutation, whatever it turns out to be physically or chemically".

It is remarkable to find that this very radical notion is advanced on almost exactly the same grounds as were used by the Mendelians of the beginning of this century to show that evolution does depend on genes. Goldschmidt is unduly preoccupied by the fact that the experimental and mathematical development of the theory of natural selection have been mainly concerned, for technical reasons, with the small-scale evolutionary differences which separate one variety from another of the same species. But it was exactly the existence of large discontinuities of variation which originally gave plausibility to the view that gene differences are important in Nature, and Goldschmidt brings forward no compelling new evidence for the rejection of this view.

One reason for Goldschmidt's distrust of genes as adequate building materials for species may be that his "rate concept" of gene action allows no place for differences in kind in the organisms produced; alterations in rate are essentially continuously variable. On the basis of the somewhat fuller theory given above, qualitative differences can easily be envisaged. According to that theory, the causal structure of an animal can be represented as a set of branching developmental paths, along each of which a certain part of the egg moves during its development. Changes in such a system would be primarily of two kinds: firstly, changes in the pattern or topological relations of the paths, which would imply an alteration in the distribution of the different portions of the egg between the various tissues, and, secondly, alterations in the actual course of the paths, which would imply that the final adult tissues were changed; and there might be combinations of these two kinds of change. Alterations of the first kind, which are typified by such a mutant as Aristopedia, would, I think, be reckoned as producing differences in kind, although it is always a matter of definition whether a change is taken as quantitative or qualitative. Differences of this sort have certainly played a large part in evolution on the grand scale, which gives rise to the major phyla.

The 'systemic' variations of Goldschmidt, that is to say the differences which separate the groups which are isolated by 'unbridgeable gaps', may also be of the second kind mentioned above. An alteration in the course of a developmental path will, if it occurs early in development, shift the whole set of paths which afterwards branch from it; that is to say, there will be a change in the character of a large number of tissues. This is the kind of difference which one most frequently finds as an 'unbridgeable gap'; it is a difference not in a few crude respects, but a permeating change in general facies. One finds genes which have similar effects within a species; for example, dachsous and rotund in Drosophila.

The 'unbridgeable' nature of the gap produced by such a gene can be understood in the following way. A developmental path has to be equilibrated; natural selection must build up a genetic background which stabilizes each path at the optimum. If, by an early-acting gene, a whole set of paths are thrown out of their old equilibria, a very considerable modification of the genetic background will be called for. Once accomplished, this will not be easily reversed or copied; and the new form will be effectively isolated from the old.

Goldschmidt's theory as to the causation of systemic variations is very unorthodox. He suggests that changes in the general pattern of an animal are caused by complex rearrangements of the chromatin. This may possibly be so, but it is a long shot in the dark. There is some evidence which seems to tell against both the essential features of such a hypothesis. In the first place some specific differences, such as that between *Drosophila melanogaster* and *D. simulans*, involve less chromosome rearrangement than may be found within a species. In the second place, there is no reliable evidence that the position effects caused by rearrangements produce more radical alterations of development than do normal gene mutations; in fact, most position effects are slight quantitative differences.

NEWS AND VIEWS

Prof. W. J. V. Osterhout

Prof. W. J. V. Osterhout has relinquished his post at the Rockefeller Institute in his seventieth year. One of the most prolific of contemporary writers on physiological subjects, Prof. Osterhout's name has been familiar to biologists since the opening years of this century. Many who associate Prof. Osterhout with problems of cell physiology may not be aware that his early interests lay elsewhere. During 1895–96 Osterhout studied in Strasburger's laboratory at Bonn and there investigated problems of nuclear cytology. Among Osterhout's contemporaries at Bonn were others destined for high place in botanical science: Prof. V. H. Blackman, recently retired from the chair of botany at the Imperial College of Science; Dr. R. A. Harper, who became professor of botany in Columbia University; and Dr. W. T. Swingle, who became a prominent member of the Bureau of Plant Industry, Washington. Those who knew him in these early days speak of the enthusiasm and zest with which Osterhout faced his life and work. These qualities have never flagged throughout a long career, and, even in retirement, we shall hope for more from his agile mind and ready pen. At the University of California, after contact with Jacques Loeb, Osterhout became engrossed in problems of cell physiology—problems which were to claim him for the rest of his very active career. Demonstrations that the then accepted facts of antagonism applied to plant, as well as animal, cells, and the development of quantitative methods for the measurement of cell permeability and the investigation of the factors which regulate this property, occupied him for many years.

Attracted by the possibilities for physiological investigation inherent in the genus Valonia, Osterhout contributed, in conjunction with a succession of research students and associates, a steady stream of papers on sap composition, salt accumulation, diffusion gradients across living membranes, bioelectric phenomena and on the investigation of diffusion and equilibria in various model systems so designed that they resemble special features of living cells. Confidence in physico-chemical interpretations of vital phenomena—in the tradition of Jacques Loeb—and a gift for ingenious experimentation, improvisation and interpretation, mark all the work with which Osterhout has been associated. These qualities were evident in one of his early books—"Experiments with Plants"—in which, in a manner still worthy of the attention of the teacher, Osterhout turned his attention to simple demonstrations of the essential facts of plant physiology. Prof. Osterhout has occupied teaching posts in the University of California and at Harvard. Many research students and post-graduate associates of Osterhout have attained prominence in American science, among them S. C. Brooks, M. M. Brooks, M. Irwin—who later became Mrs. Osterhout—L. R. Blinks and others. Latterly the claims of research ousted more general teaching. Since 1925, Prof. Osterhout has served the Rockefeller Institute, has been a trustee of the Wood's Hole Marine Biological Laboratory and a member of the editorial board of the *Journal of General Physiology*, in which much of his work is to be found. Future students of general physiology will not fail to see in Prof. Osterhout one of the outstanding figures of his day, and, as he relinquishes his post, his contemporaries wish him well.

University of Bristol: Air Raid Damage

The most serious damage to the University of Bristol during recent air raids was the loss of the Great Hall, gutted by fire. This hall, opened by the King in 1925, was a fine architectural feature with a hammer-beam roof and linenfold panelling of old English oak. With other buildings in the same block, it was the gift of Messrs. G. A. and H. H. Wills, and wood and stone carvers of the highest skill were brought from all parts of Great Britain for its construction. Since the arrival of King's College, London, the Hall had been used as a library and reading room for King's students, and the books it contained were all destroyed. A lecture room in the same building was also burnt. Another building which has been burnt out housed the anatomical dissecting room and theatre, portions of the Department of Geography and a unique collection of finds and exhibits of the Spelæological Society, which for many years has been active in the exploration of Mendip caves. The efforts of the A.R.P. guard, headed by Prof. C. M. Yonge, prevented fires from spreading to other departments. The roof of a new building to be used as an extension of the Library was burnt, but fortunately the University had not yet transferred any material into it. Other buildings, including the laboratories of physics and chemistry, suffered loss of windows by blast.

Bristol Museum and Art Gallery

The front part of the Natural History Museum, Bristol, which is an old building, has been entirely gutted by fire. The Geological Department was destroyed, but type specimens and much material in store were saved. Unfortunately, the fine collection of fossil saurian skeletons, especially those from the Lias of Street and Lyme Regis have been lost. The Zoology Department suffered considerably, but there is sufficient material left for reconstruction. Cases and contents in botany have gone, but some of the herbaria are intact. Cases and about half the contents, including glass and china, in the George Wills Hall have been destroyed.

An 1820 building which was the early home of the Bristol Institution and Museum and of the Literary and Philosophical Society was also gutted by fire. Humphry Davy contributed many lectures to the weekly series of the Society, of which Faraday and James Watt were honorary members.

Goldsmiths' College

GOLDSMITHS' College, which was severely damaged during a recent air raid, has an interesting history. The oldest part of the building represents what is left of the Royal Naval School, founded in 1833 as a public school to enable the less affluent naval officer to give his sons a sound education at the least possible expense. Nearly sixty years later the Goldsmiths' Company took over the premises, and established its Technical and Recreative Institute, providing, besides numerous technical classes, science and art departments which gained a high reputation. The latter attracted distinguished artists as teachers, whilst in the science department the late Sir William Pope, the late Prof. G. Barger of Edinburgh, and Prof. A. Lapworth of Manchester, were among those who gained their earlier experience in teaching. At the end of a period of thirteen years, the Act of 1902 having meantime thrown the responsibility for providing technical education upon the London County Council, the Company closed the Institute, and handed over the premises and site to the University of London on liberal terms. The University retained the Art and Science and Engineering Departments, and, with the co-operation of several county authorities, established a large Training Department.

Thus the Goldsmiths' Institute became Goldsmiths' College, owned and controlled by the University. The Science Department was closed during the War of 1914–18. Later on, the Engineering Department was removed to the new South-east London Technical Institute by the London County Council, and was replaced by an Evening Department of Adult Education. On the outbreak of the present war, the Training Department was transferred to Nottingham. As stated above, the College has been severely damaged. The upper floor, including the library and common rooms, has suffered very heavily. Fortunately, the Great Hall, capable of seating about 1,800 persons, and the organ, upon the renovation of which a sum of several thousand pounds has recently been spent, remain intact. The Art School, built at great expense only a few years ago, is also uninjured. It is to be hoped, therefore, that Goldsmiths' College will in happier times be enabled to resume its former activities.

Drug Supplies in War-Time

INSTEAD of the customary science paper, the January meeting of the Pharmaceutical Society's winter session, held on January 16, was devoted to the topical subject of the drug supply in war-time. The speaker, Mr. Arthur Mortimer, whose world survey of the medicinal products used in Great Britain —a survey prepared for use in the event of an emergency—has proved a helpful piece of work to Government departments, referred among other matters to drugs which are now scarce because their usual sources are no longer available, and to other sources of supply. It has been necessary, he said, to consider how far potassium salts can be replaced by sodium salts; the home supply of potash is very small and Great Britain has been mainly dependent upon Central Europe for its supplies, although since the War of 1914–18 arrangements have been made by British manufacturers to develop the Dead Sea deposits. It is obvious, he said, that for many uses sodium bromide can be as effective as potassium bromide. Regarding vegetable drugs he mentioned gentian, squill, liquorice, senega, cassia, belladonna, hyoscyamus, stramonium and colchicum, among others, which are already in short supply or may be in short supply, "though if care is used and substitutes are prescribed wherever possible, we shall have no difficulty in meeting the situation". Referring to the manufacture in Great Britain of synthetic products which in the past were made exclusively in what are now hostile countries, he said that H.M. Government naturally expects that every British pharmacist throughout the Empire "would refuse to keep enemy trade marks warm" and would do all they could to popularize the British remedies which are now available.

Polish Faculty of Medicine at Edinburgh

THE University of Edinburgh is providing facilities for the Polish Government to establish a Polish School of Medicine at Edinburgh. This will be staffed by professors and teachers now serving with the Polish Army in Great Britain and by professors of the University Faculty of Medicine in such subjects as may not be represented among the Polish staff. The Polish Forces in the country include a considerable number of medical men, of whom many are of high academic standing, and have held important teaching and research appointments in Poland. In addition, there are other medical graduates of Polish universities and Polish medical undergraduates whose work will be seriously affected unless something is done to mitigate the unfortunate situation in which these men now find themselves. As it is the proclaimed intention of Germany to abolish all higher education in Poland, that country will be left destitute of all means, human and material, for university teaching. By the formation of a Polish Faculty of Medicine, an important branch of Polish learning, namely, medical research and teaching, may be kept alive.

Concessions to School Certificate Candidates

CONCESSIONS to candidates for the 1941 School and Higher School Certificate examinations have been announced by the Board of Education. No abbreviation or reduction in standard of the syllabuses is demanded, but a wider choice of questions will be given so that candidates who, from unavoidable causes, have been unable to cover the whole ground, may yet have ample opportunity of showing their proficiency. The methods for conducting the examinations for admission to secondary and junior technical schools in 1941 will be the same as in 1940, and suggestions have been made for lightening the amount of work thrown upon education authorities in reception areas, whose staffs have already been depleted.

Overseas Students in Great Britain

IN the review of Mr. E. Child's book "The Tools of the Chemist" in NATURE of November 9, p. 604, reference was made to the necessity of bringing students from overseas to Great Britain after the War; and the suggestion was made that this should form part of the work of the British Council. Prof. B. Ifor Evans, Educational Adviser to the British Council, now writes that, since 1935, the British Council has been inviting students from overseas to undertake courses and research at British universities and similar institutions; indeed, had not the War prevented it, nearly 250 students from twenty-one countries would have commenced their studies in Great Britain in October 1939. Drawn from practically all countries of Europe, many countries of South America, the Dominions and Colonies and the Near and Middle East, these students would have studied or carried out research in a great variety of scientific and humanistic subjects, including medicine, engineering, agriculture, law, philology, economics, sociology, physics, education, English language and literature, etc. Such activity is continuing so far as possible, even during the War; last year 143 students from overseas studied in the United Kingdom under the auspices of the British Council, and after the War it is hoped to give a considerable extension to this work.

The American Contribution to a New Order

IN an address at Southampton, Long Island, on September 1 on "Our United States in this Backward Moving World", Dr. N. Murray Butler asserted that the human race is witnessing the greatest and most far-reaching revolution which history records. This revolution is primarily the outgrowth of economic problems and ambitions, and he urged that the substitution of information for knowledge as a result of the influence of the Press and the radio has made it of vital importance to look beneath the surface of things. The arrest at the beginning of this century of progress towards a prosperous and contented and peaceful world, organized for the preservation and protection of law and order, was due to the incompetence and failure of the democracies, especially France, Great Britain and the United States, to understand the new economic and political forces at work and to co-operate for their control and direction in a manner which would preserve and protect the democratic system of economic, social and political order, as well as the free institutions built upon that order.

In these critical years the democracies lacked conspicuously the able, constructive and courageous leadership required. Discussing the causes for the absence of co-operation, courage and vision in the democracies, Dr. Butler pointed out that all those important problems and policies which have been looked upon in the United States as national or domestic are now absorbed into and made part of the world revolution. This change must be recognized, as well as the danger incurred, for the public opinion and elected political representatives in the United States come under the pressure of closely organized and persistent minority groups, unconcerned with principles or the public welfare.

Public opinion, moreover, is the unseen product of education and practical experience. Education, in turn, is the function of the family, the church and the school in co-operation. The neglect or failure of the family in its guiding influence and discipline, and of the church in its religious instruction, has given an impossible burden to the schools, and these conditions must be corrected if the American people are not to play into the hands of the advocates of a totalitarian State. Dr. Butler further referred to the signs of an incapacity to understand and to interpret liberty, or to distinguish it from licence. The limit between liberty and licence must be recognized and observed if liberty itself is to remain. In this backward-moving world, however, Dr. Butler believes that leadership towards return to a new and forward-moving world may well rest with the United States. despite its shortcomings and failures. The federal principle it has established must be applied further if a new, prosperous and peaceful world is to be established upon the wreck of the present order.

Engineers and Reconstructions

AT a meeting of the Junior Institution of Engineers on December 14, Viscount Falmouth in his presidential address pointed out that, after the War, a heavy weight of responsibility will still lie on the shoulders of the engineer, for, though the planning of reconstruction may be in other hands, the methods and the actual work of restoring a stricken world will fall largely to the man of science and the engineer. When the Napoleonic wars left England and Europe in a state of profound exhaustion, it must have seemed impossible that recovery could take place for a long time. But depression lifted gradually, first in Great Britain and later in Europe, largely due to the development by James Watt of his steam engine. After 1918, Great Britain was again exhausted by the immensity of her effort; but although we had several severe economic storms to weather, yet, on the whole, our recovery was fairly rapid. Although this time we did not have an entirely new prime mover to come to our assistance, as we had in 1815, yet the years 1918–30 saw the large steam turbine reach a high state of efficiency and trustworthiness. This, doubtless, contributed to the national recovery. The fact that power from a thermal unit can be sold as cheaply as power from a hydro-electric station, has enabled Great Britain, with its small water-power resources, still to compete with countries better placed in this respect.

To-day we ask ourselves if there is any form of prime mover which is likely to do for our generation what the Watt engine did for the years after 1815 and the Parsons steam turbine did from 1918 onwards. Possibly the high compression internal combustion engine may be an answer. This has a high thermal efficiency, and, as now constructed, is most trustworthy. The fact that it can operate on either oil or gas without even changing the compression ratio gives it an important flexibility. Besides the assistance given to the world by the supply of cheap power in huge quantities after the War of 1914–18, the years since have seen a great development in the methods of manufacture. One lesson we must learn from the present War is that we must no longer neglect the manufacture of high-grade machine tools. The reasons are not necessarily technical; they are more in the economic field, but the high reputation we now have for very elaborate products should leave no one in doubt in the future that we can turn out small-grade machine tools of an excellent quality.

50-Million Volt Cyclotron to be Built in Moscow

THE construction of a very powerful cyclotron, capable of producing 50 million electron volt deuterons, will be commenced in Moscow early in 1941, according to a decision of the Academy of Sciences of the U.S.S.R., based on a report submitted by the Physical Institute of the Academy. A magnet the core of which weighs about 1,000 tons and solenoid of 18 tons is to be installed. A special building to house the cyclotron will be erected in the grounds of the new home of the Physical Institute of the Academy being built on the Bolshaya Kaluzhskaya Ulitsa in Moscow. The old apparatus in the Soviet Union, which is in the Radium Institute of Leningrad, is capable of giving an energy of 4 million electron volts to particles; another, nearing completion at the Physico-Technical Institute, also in Leningrad, will be capable of imparting an energy of 10–12 million electron volts.

Fossil Skeleton of Uintatherium

AN almost complete skeleton of Uintatherium, a six-horned animal the size of an elephant which dominated the primitive forests of southern Wyoming about thirty million years ago, has been found by Dr. Charles L. Gazin, palæontologist of the Smithsonian Institution. Bones of this giant mammal are common; but a skeleton with only a few parts missing is rare. Dr. Gazin's find lacks only one hind leg, part of a foreleg, and the neck vertebræ. The skull, about three feet long, is in exceptionally good condition, although the lower jaw is considerably crushed. There is also a second skull, including one of the beast's sabre-like down-pointed tusks about a foot long. The skeleton is expected to become one of the main exhibits in the U.S. National Museum, after it has been worked free from the matrix of hardened clay in which it is embedded, and properly mounted. This work may require as much as a year.

Recent Earthquakes

AN earthquake of considerable severity shook the island of New Britain, which is to the north-east of New Guinea, early on January 14. The epicentre appears to have been near Keravat, where houses collapsed. Keravat is some twenty-five miles from the port of Rabaul, where some faulting occurred, damaging the harbour. An earthquake of intensity 7 or 8 on the Rossi-Forel scale was felt at Rabaul on September 12, 1940, at 11.20 p.m. local time, the shock lasting for some three minutes and then decreasing in severity. Seventy-two distinct tremors were felt between then and 8.30 a.m. on September 13. The epicentre was judged to be about 70 miles south-south-east of Rabaul, and the shock was severely felt in the Kokopo District and at Wide Bay, Pondo, Namatanai and Buka.

On December 12 an earthquake was registered on the short-period instruments at Kew Observatory at 21h. 20m. 41s. G.M.T. There were only slight traces on the Galitzin seismograms. The earthquake was calculated to have had its epicentre some 290 km. distant from Kew and was thus a 'near' earthquake. About this time a shock was reported from Penrhos in North Wales. On December 28 a moderately strong earthquake, giving maximum ground amplitude of 21 μ was registered at 16h. 51m. 54s. G.M.T. It was calculated to have had its epicentre some 11,600 km. away and was thus a 'distant' earthquake. A full suite of well-registered waves was observed.

Announcements

SIR WILLIAM BEVERIDGE, who has been chairman of the man-power survey of the Ministry of Labour and National Service, has been appointed an under-secretary in the Ministry. It is stated that the man-power survey has been completed, and Sir William Beveridge will now have administrative responsibility for the section of the Ministry dealing with man-power requirements of industry and the Armed Forces.

MRS. NEVILLE-ROLFE, secretary-general of the British Social Hygiene Council, has been awarded the Snow Medal for 1941 by the American Social Hygiene Association. The medal is given for "distinguished service to humanity", and is named after Dr. Snow, the first director of the American Association, founded in 1913. Mrs. Neville-Rolfe is the fourth recipient of the medal and the first woman to receive it.

OWING to war conditions, the Industrial Health Education Society, which started its activities in 1927, has resolved to close down its work in arranging for talks on the requirements for industrial health. Its remaining funds are being handed over to the British Medical Association to establish a Mackenzie Lectureship on industrial hygiene in memory of Sir James Mackenzie, who began the work.

THE Clough Memorial Research Fund was instituted in 1935 for the purpose of encouraging geological research in Scotland and the North of England. The North of England is defined as comprising the counties of Northumberland, Cumberland, Durham, Westmorland, and Yorkshire. Under the terms of administration of the fund a sum of approximately £30 is available annually. Applications for grants are invited for the period April 1, 1941–March 31, 1942, and should be made to the Secretary, Clough Research Fund Committee, Edinburgh Geological Society, Synod Hall, Castle Terrace, Edinburgh, not later than March 1.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

The Protein of Insect Cuticle

Odier[1], Wigglesworth[2], Pryor[3] and others have demonstrated the presence of protein in the cuticle of various insects. The most modern study is that of Fraenkel and Rudall[4] using material from the prepupal and pupal stages of the blowfly *Sarcophaga falculata*. They showed that in the larval stage the cuticle contains a high proportion of a protein which is very soluble in water. On pupation more protein is added and the process of melanization is correlated with hardening, water loss and the loss of solubility of the protein.

TABLE 1.

Preparation	Total N. %	Ammonia N. % of total	Base N. % of total	Monoamino N. % of total
Sarcophaga larval protein	15·0	6·2	23·0	72·4
,, ,, cuticle	—	—	20·5	75·2
,, puparia	—	—	21·5	68·0
Sphinx ligustri protein I	15·1	8·5	19·5	73·0
,, ,, ,, II	11·4	—	—	—
Lobster cuticle protein	15·4	9·5	18·1	70·4
Sericin *A* (see Scott[5])		12·14	16·56	70·1
Sericin *B* (see Scott[5])		10·22	18·20	69·2

Since then I have been able to characterize the larval cuticle protein in *Sarcophaga falculata* and show its relation to the cuticle protein at other stages of the life-history and in other arthropods. Table 1 shows the nitrogen distribution in the preparations analysed.

TABLE 2.

Preparation	Tyrosine %	Tryptophane %	Glycine %	Sulphur %	Carbohydrate (as glucose) %	Amino sugar %	Phosphorus %
Sarcophaga larval cuticle ..	—	—	—	0·56	0·40	—	—
,, ,, protein ..	5·2	1·4	0·67	0·0	0·0	positive	0·0
Sphinx larval cuticle ..	—	—	—	0·30	0·81	—	—
,, ,, protein I ..	12·0	positive	1·32	0·34	0·0	0·0	0·0
,, ,, ,, II ..	—	—	—	0·51	2·86	positive	—
Lobster cuticle protein ..	6·0	positive	—	positive	positive	—	—
Sericin (Alders[6])	6·0	1·0	—	positive	—	—	—

Table 2 gives figures for specific components.

The general physical properties, nitrogen distribution and absence of sulphur suggested that the protein was similar to gelatin. However, the presence of considerable quantities of tyrosine and tryptophane indicated a marked difference (gelatin contains only traces of both amino acids) which is borne out by the very low glycine content. The tables show, however, that this and other arthropod cuticle proteins resemble sericin (silk gelatin) quite closely. This is understood, when it is remembered that the silk glands and the hypodermal cells secreting the cuticle are both epidermal in origin.

A study of the nitrogen distribution in the whole cuticle showed that both in the larva and the pupa the greater part of the non-chitin portion of the cuticle in *Sarcophaga falculata* is similar to the protein isolated from the larva. Observations on the melanin of the pupa substantiate the view of other workers that it is derived from tyrosine and is responsible for binding the chitin and protein together into a very compact and resistant complex.

Such proteins may be universal in the insect cuticle. Substances showing a general resemblance to the above have been obtained from a number of different arthropods, and figures are given in Tables 1 and 2 for those from the hawk moth (*Sphinx ligustri*) and the lobster.

The protein from Sarcophaga larvæ contains a trace of amino sugar but no carbohydrate or sulphur; though the intact cuticle contains small but definite quantities of both the latter. This suggests that there may be a carbohydrate-rich fraction in the cuticle other than the chitin itself. In this respect the hawk moth cuticle is similar; by extracting 'chitin' residues (after removing the very soluble protein I) with a more powerfully disrupting reagent it was possible to obtain a protein fraction II which contained amino sugar and was much richer in carbohydrate and sulphur than the whole cuticle. The chitin residue after this treatment had slightly lower than the calculated nitrogen content and contained no further protein, but still contained traces of sulphur and non-amino carbohydrate. The nature of the sulphur, which is combined, has not been definitely established.

The evidence supports the view that the carbohydrate and sulphur (possibly ethereal sulphate sulphur) are concerned in linking the protein to the chitin, which has, until now, been regarded as a neutral polysaccharide. It may now be tentatively suggested that the protein and chitin are linked in a similar way to that in the known mucoproteins (see Meyer[7]). It is interesting that Dr. K. M. Rudall (private communication), working on the same problem using X-ray analysis, now has evidence for a definite but weak chemical link between protein and chitin in the larval cuticle of *Sarcophaga falculata*.

This work suggests a chemical similarity between the chitin-protein complex of the insect cuticle and the known mucopolysaccharide-protein aggregates. It throws light on the problem of chitin formation, and shows that the cuticle is composed of components of the nature postulated from the properties of the cuticle now under investigation by Hurst[8] in his studies of insecticidal action.

This work was made possible by a grant from the Agricultural Research Council and has been carried out in the Biochemical Laboratory and the Biological Field Station of the Imperial College of Science and Technology. I am greatly indebted to Prof. A. C. Chibnall and to Prof. J. W. Munro for their continued interest and encouragement. I must also thank Drs. K. M. Rudall and G. Fraenkel for their interest and help.

Permeability of Insect Cuticle

IN a recent communication[1] Hurst has described a series of important observations which go far to explain the action of non-toxic paraffins in facilitating the penetration of insecticides through the cuticle of insects. He provides evidence that "apolar substances of low dielectric constant" greatly increase the permeability of the outer lipoid layer of the cuticle.

I have recently obtained confirmation of this view in the following way. A small insect, such as a flea or louse, is immersed in oil and examined under the microscope. Within a few minutes if xylol is used, within half an hour or so if medicinal paraffin or olive oil is used, minute droplets of water begin to appear all over the cuticle; often most markedly on the hardest parts, such as the claws of the louse. Presumably polar substances of some kind crowd into the oil-water interface as the lipoid layer dissolves, and thus draw out the water droplets.

If such an insect is immersed in a mixture of ethyl alcohol and kerosene as described by Hurst, and watched under the microscope, the droplets swell up and separate with such violence that the insect seems to be effervescing. This, of course, is because in the presence of traces of water the alcohol separates from the paraffin. The same thing is seen, among other mixtures, in kerosene and acetone, carbon disulphide and ethyl alcohol, medicinal paraffin and butyl alcohol and, less violently, in medicinal paraffin and pyridine or dodecyl thiocyanate and pyridine. In benzene and ethyl alcohol diffusion currents appear over the cuticle but few droplets separate.

Besides substantiating Hurst's valuable discovery, these observations stress the importance of the partition coefficient of a substance between oil and water in determining the rate at which it will leave the oily base of a contact insecticide and enter the tissues of an insect. This simple conception may prove helpful for the rational selection of active principles and solvents in the preparation of contact insecticides.

Sex-Ratio in *Urosalpinx cinerea*, the American Oyster Drill

IN the course of preliminary studies of the biology of the introduced American oyster drill, *Urosalpinx cinerea*, it was noticed that among drills kept in a tank at Conway a very large proportion of the medium-sized and large individuals deposited egg-capsules. This led to an investigation of the sex-ratio in this mollusc, the results of which are described briefly below. The sex of Urosalpinx is easily determined macroscopically, for the male has a comparatively large curved penis lying behind and slightly to the right of the head; in addition the gonad of the female is yellow or orange, while that of the male is whitish. Although Urosalpinx has been closely studied in the United States[1,2], no information is available concerning the sex-ratio.

Sex has been determined in a total of 1,946 drills belonging to sixteen samples dredged from the oyster beds in the Rivers Blackwater, Colne, Roach and Crouch. Of this total, 1,381 were females and 565 males, that is, females predominated to the extent of 71 per cent. In addition to this general preponderance of females there are also marked variations in the proportions of the two sexes in drills of different sizes. During the spring when the drills are spawning, there are about equal numbers of males and females among those with shells 2·3 cm. or less in height (Table 1); these drills can be stated with certainty to be one year old. It is doubtful whether the females deposit spawn at this age. Drills two years old are generally about 2·5 cm. in height during the spring, while three-year-olds average about 2·9 cm. Among these two- and three-year-old drills the percentage of females varies somewhat, but is generally between 60 and 70 per cent (Table 1). Drills more than 3·0 cm. in height at the beginning of the spawning season may be reckoned as four years old or more; among these large drills the percentage of females increases rapidly with height of shell and approaches 100 per cent. Males are very scarce among drills over 3·2 cm. but are not entirely absent. The largest drill examined was a female 4·3 cm. in height, but males between 3·5 and 3·8 cm. occur occasionally. Such very large drills must be at least six years old.

TABLE 1.—*Urosalpinx cinerea* FROM RIVER BLACKWATER, ESSEX, MAY 15, 1939.

Height	♀♀	♂♂	Total	% ♀♀
2·3 cm. and less	8	6	14	57·2
2·4 cm.	1	1	2	50
2·5 cm.	11	8	19	57·9
2·6 cm.	9	5	14	64·3
2·7 cm.	7	4	11	63·6
2·8 cm.	11	1	12	91·6
2·9 cm.	9	7	16	56·3
3·0 cm.	9	5	14	64·3
3·1 cm.	7	1	8	87·5
3·2 cm.	8	2	10	80
3·3 cm.	8	–	8	100
3·4 cm.	10	–	10	100
3·5 cm.	9	–	9	100
3·6 cm.	7	1	8	87·5
3·7 cm.	3	–	3	100
3·8 cm.	3	–	3	100
3·9 cm.	1	–	1	100
4·0 cm.	2	–	2	100
4·3 cm.	1	–	1	100
Totals	124	41	165	75·2

The percentages quoted above refer to conditions obtaining during the early part of the breeding season, which begins in late April or early May, reaches its peak during late May or early June, and thereafter declines in intensity. Whereas the percentage of females only slightly exceeds 50 per cent both before and after the spawning season, at its height in late May and during June the proportion of females reaches very high figures indeed, 95 per cent being obtained in one sample, while figures of 80–90 per cent are quite frequent (Table 2). The percentage of females therefore varies directly as the intensity of spawning, reaching a peak in June when most egg-capsules are deposited.

Many of the observed peculiarities in the sex-ratio would be explained if it could be shown that the oyster-dredge, by means of which the samples were collected, does not give an even sample of the population of drills, and that females are more liable to capture during the breeding season than males. It is known that the females tend to crawl on to raised objects on the sea bottom in order to deposit spawn, and therefore as the intensity of spawning increased more and more females would be found upon raised objects. It is, however, highly probable that the scraping bar of an oyster dredge collects practically everything in its path from the surface of the bed and not merely the most upstanding objects. Further, although nothing is known of the behaviour of the males during the spawning season, it is reasonable to assume that they follow the females. The constant high percentage of females among very large drills, even outside the breeding season, might be explained on the basis of sexual dimorphism, which is stated to occur in Urosalpinx in America, although the occurrence of isolated very large males (Table 1) is rather disconcerting.

TABLE 2.—SEASONAL VARIATION IN THE PERCENTAGE OF FEMALES IN SAMPLES OF *Urosalpinx cinerea* FROM THE RIVER BLACKWATER, ESSEX. ONLY THOSE DRILLS OVER 2·3 CM. IN HEIGHT, THAT IS, TWO YEARS OLD OR OLDER, ARE INCLUDED.

Date	♀♀	♂♂	Total	% ♀♀
7.4.38	50	42	92	54·4
10.4.40	12	13	25	48·0
2.5.40	66	46	112	58·9
15.5.39	117	35	152	77·0
15.5.40	243	33	276	88·0
13.6.40	57	3	60	95·0
14.6.40	124	18	142	87·3
20.6.40	31	22	53	58·5
2.7.40	80	28	108	74·1
15.7.39	122	58	180	67·8
26.8.40	54	37	91	59·3

For the reasons outlined above it is considered that an explanation of the peculiar sex-ratio in dredged catches of Urosalpinx, based solely on the possibility of a selective capture-rate during the breeding season, is unconvincing. An alternative explanation would involve actual changes in the sex-ratio due to sex-change in a part of the population both before and after the breeding season. This is by no means out of the question but is subject to experimental testing, for which an opportunity may be available next spring when the drills again become active following the winter period of quiescence.

Cytology and Taxonomy of Hebe, Veronica and Pygmæa

CYTOLOGICAL evidence has materially assisted towards clarifying taxonomic relationships in a large number of genera. As a rule, systematic and cytological approaches have led to conclusions which were in general agreement. Recent cytological work on the related genera Hebe and Veronica, however, pointed to a discrepancy between cytological and taxonomic evidence. This has now been removed by the discovery that the latter was based on erroneous observations.

Pennell[1], reviving Commerson's genus Hebe, separated it from Veronica L. Cockayne and Allan[2] transferred to Hebe the majority of the species endemic in New Zealand, but left in Veronica the group that Cheeseman[3] had placed in Euveronica. The species so placed by Cheeseman are confined to New Zealand, as is the large majority of the species transferred to Hebe. Pennell used the subspecies name Euveronica for a group within his circumscription of Veronica proper, with *V. officinalis* as the type species. The principal reasons for the retention of Cheeseman's Euveronica in Veronica were their manner of capsule dehiscence and the shape of their capsule, in both of which, following Hooker[4], the species grouped in Euveronica were held to be Veronicas rather than Hebes.

Frankel and Hair[5] found that the basic chromosome numbers of Hebe are 20 and 21. A large number of species was studied (Frankel, unpublished); without exception they range in two polyploid series, one more numerous, based on $x = 20$, the other on $x = 21$. The highest chromosome number is the hexaploid, $2n = 120$. Huber's[6] observation of $2n = 24$ for *H. diosmæfolia* is doubtless erroneous, its chromosome number being $2n = 40$. For those New Zealand species which were left in the genus Veronica, Frankel and Hair found $n = 20$ and $n = 21$. These chromosome numbers for Hebe and for Cheeseman's division Euveronica differ widely from those of the great majority of species of Veronica, including Pennell's Euveronica, with a main distribution in the northern hemisphere (cf. Lehmann[7]). They have, therefore a twofold significance. First, they support the establishment of Hebe as a separate genus, and second, they strongly indicate a close relationship between Hebe and Cheeseman's Euveronica, closer indeed than that between his Euveronica and any other section of Veronica. Yet, owing to its capsule being of the Veronica type, on taxonomic grounds this group had to remain in Veronica. Thus a clash appeared between the natural relationship as revealed by cytological evidence and distribution, and the taxonomic classification on morphological grounds.

In view of this contradiction, Allan[8] recently examined the capsule dehiscence of indigenous and introduced Veronicas. Whilst in the latter it followed along the lines described by Hooker, "in the New Zealand species placed by Cheeseman in Euveronica, . . . the dehiscence is essentially as in Hebe . . . the group thus occupies a somewhat intermediate position, but is much closer to Hebe proper than Euveronica (cf. Pennell)". Consequently Allan transferred the New Zealand species of Euveronica to Hebe. Thus in this case attention was directed by cytological data to a wrong classification which was due to erroneous observations.

The question must now be asked what should be the taxonomic position of the third group of New Zealand species related to Veronica, namely, Pygmæa. Founded as a separate genus by Hooker, reduced to a section of Veronica by Cheeseman, it received again generic rank from Cockayne[9]. The capsule characters of Pygmæa correspond to those of Hebe, its main distinguishing marks being its growth habit. All three species are small, depressed pulvinate herbs with minute, densely imbricated leaves all round the branches, and their corolla limb has five lobes instead of the four of Hebe. The chromosome numbers of two species, *P. pulvinaris* and *P. Thomsoni*, have now been established as $n = 21$, indicating again a close relationship with Hebe. It must be asked whether this obvious relationship in the 'genetic system' should not be expressed by the inclusion of Pygmæa in Hebe, whilst acknowledging its distinctiveness by the formation of a section of Pygmæa.

In cases such as this, cytological evidence is sufficiently convincing to establish taxonomic relationships which on morphological grounds alone are obscure.

Quantum X-Ray Reflection in Diamond

IT has been shown[1] that, corresponding to the usual formula,

$$2\,d \sin \theta = n\,\lambda \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

for the classical or unmodified reflection of X-rays, the general geometric law of modified or quantum reflection by crystals is

$$2\,d \sin \psi \sin (I + \varepsilon) = n\,\lambda \sin I \quad . \quad (2)$$

θ and ψ are here the glancing angles of incidence on the static and dynamic stratifications measured in the respective planes of incidence, ε is the angle between these stratifications, and I the inclination of the phase-waves of the lattice vibration to the static crystal planes. The two planes of incidence would coincide when the equations are simultaneously satisfied, and more generally also when the observations are made in a plane of the symmetry of the crystal. We may then write $2\,\psi = (\varphi + \theta)$ and $2\,\varepsilon = (\varphi - \theta)$, where θ and φ are the glancing angles of incidence and of quantum reflection measured with reference to the static crystal planes. The angle I in equation (2) is thus capable of being evaluated directly from observations of the Laue and the quantum reflections over a sufficient range of incidences. If I is $\pi/2$, equation (2) reduces to

$$2\,d \sin \tfrac{1}{2}\,(\varphi + \theta) = n\,\lambda \quad . \quad . \quad . \quad . \quad (3)$$

as a close approximation.

Careful measurements made by us of the modified reflections given by sodium nitrate, rock salt and calcite are in good agreement with equation (3). It may therefore be inferred that in these crystals, and probably also in ionic crystals generally, the phase-waves are transverse to the crystal spacings. Very early in our investigations, it was noticed that formula (3) fails to fit the observations on the 111 reflections of diamond. These are sharp and can be accurately measured, and, when φ and θ differ greatly, it is found that the observed values of φ are much nearer θ than those given by the formula. From a new series of measurements made over a wide range of incidences, we find that the observations fit the rigorous formula (2) perfectly, the angle I coming out as 55° ± 1°. This is half the tetrahedral valency angle, thus indicating that the phase-waves of the lattice vibration giving the modified reflections from the (111) planes of diamond are parallel to the (100) planes of the crystal lattice.

As has already been pointed out[2], the influence of temperature on the quantum reflections should be wholly different in the two cases $h\nu^* \gg KT$ and $h\nu^* \ll KT$, where ν^* is the frequency of the lattice vibration. The case of diamond belongs to the first category and we should accordingly expect that the intensity of the reflections should practically be unaffected by being cooled down to liquid air temperatures. Our experiments to test this point have been completed and completely confirm the theoretical expectations.

'Historical Materialism'

IN the notice of Dr. Federn's recent book "The Materialist Conception of History" published in NATURE of November 9, the reviewer, while deploring the interest of "the non-historical younger part of our people" in historical materialism, sums up his own attitude, and that of "generations of better historians than Marx". in the statement that "mind and not matter rules the world". If this is meant to imply that mind or the human will can act as an independent agent, then it is in striking contrast to the attitude expressed by Prof. Einstein in his article on "Science and Religion" in the same issue of NATURE. In discussing the "regularities obtaining within the realm of living things", which presumably includes human history, Prof. Einstein says, "For him [a man imbued with the ordered regularity of all events] neither the rule of human nor the rule of Divine Will exists as an independent cause of natural events."

The opinion of Marx and Engels on this question was clearly expressed in a letter from Engels to J. Bloch[1]: "We make our own history but in the first place under very definite presuppositions and conditions. Among these the economic ones are finally decisive. But the political, etc., ones and indeed even the traditions which haunt human minds, also play a part though not the decisive one."

I believe that the attitude expressed in the above quotations commands a great deal more sympathy among the younger men of science and even historians than the purely idealist position of Mr. Marvin. At the present time, when everyone is deeply concerned to understand the forces behind contemporary history, and events themselves are forcing us to attempt to analyse society, historical materialism deserves a serious evaluation.

Cultural Significance of Science

THE admonition in NATURE of December 28 to abandon "once and for all the belief that science is set apart from all other social interests as if it possessed a peculiar holiness" expresses very precisely the opposite of what many men of science consider to be their duty. I, for one, can recognize nothing more holy than scientific truth, and consider it a danger to science and to humanity if the pursuit of pure science, regardless of society, is denied by a representative organ of science.

For the last ten years we have been presented by an influential school of thought with phrases about the desirability of a social control of science, accompanied by attacks on the alleged snobbishness and irresponsibility of scientific detachment. The 'social control of science' has proved a meaningless phrase. Science exists only to that extent to which the search for truth is not socially controlled. And therein lies the purpose of scientific detachment. It is of the same character as the independence of the witness, of the jury, of the judge; of the political speaker and the voter; of the writer and teacher and their public; it forms part of the liberties for which every man with an idea of truth and every man with a pride in the dignity of his soul has fought since the beginning of society.

This struggle is to-day at its height; on its outcome will depend, among other great issues of a kindred nature, whether scientific detachment and the civilization pledged to respect and cultivate pure science shall perish from this earth.

Science and Government

ARTICLES have recently appeared in NATURE referring to what life ought to be like after the war. Other journals have also discussed the same subject. Each writer, theologian, socialist or whatever he is, feels sure that there will be a change and that his views will then get due recognition. All may agree that after this great conflict we shall not settle down again into the same old ways. Let us hope that science may then come into its own.

There was a time when 'science' was 'falsely so called'—that time has passed with the Dark Ages. Then came the twilight of the Renaissance. Now we are living in the daylight of the new day which has dawned on the world. The pious guesses and folk-lore of the past—to be revered as showing the stages of human evolution and inspiration—must now be replaced by the certainties and accuracies of science.

For a hundred years success has attended engineering and chemical enterprises which were guided by scientific methods, and what is urgently required is that science shall control not merely our factories but gradually all activities which come within its ambit—efficiency and economy being the objectives. Instead of party government we require scientific government. Thus may science prove the unifier of man, and usher in an era of universal peace. Individual health and happiness will also be secured by the application of scientific principles. But how can science obtain the control to which it is entitled?

RESEARCH ITEMS

Early House-Types in Wales

Examination of a croft site, Nant-y-Moch, in the Upper Nedd (Neath) valley, Ystradfellte, Brecknockshire, has led Sir Cyril Fox to certain conclusions as to possible prototypes of the Long-House in Wales (*Antiquity*, December 1940). The site lies at a point in the valley 1,250 ft. above Ordnance datum in an upland region such as was much sought after by early man, and where, it is known, was a meeting place of the *B* (Wessex) and *A* (East Anglian) Beaker cultures. The house stood on a narrow shelf, its long axis being at right angles to the contours and the upper part deeply excavated in the side of a rapidly steepening hill. It is in ruins, and certain structural features are obscure. It is built on an artificial platform on two levels, of which the upper end is much below, and the lower end slightly above, the natural level of the natural surface. Probably the length of the upper half was not less than 20 ft., the breadth only 12 ft., but at the southern end increasing to 17–18 ft. with a roof span slightly in excess. The total length was probably not less than 55 ft. A cross-wall divides the upper and lower houses. The excavation into the hillside is horseshoe-shaped and revetted rectangularly. The lower house is stone-walled. It belongs to the group of "long-houses" of which the essential features are a cowhouse under the same roof as the dwelling-house, and usually at a lower level with direct communication by means of a passage. Such houses are still numerous in Carmarthenshire and afford close parallels. A striking feature is the construction of the dwelling on a tilt. The earlier are structurally single. The change from excavated area to platform corresponds with the division between the upper and lower houses and the entrance to the upper house. Nant-y-moch is probably a long-house embodying features not hitherto recognized as elements of the type; and it may prove to be the prototype or one of the prototypes of that house in Wales.

Apache-Pueblo Culture Elements

Investigation of the culture elements of the Apache-Pueblo group of the south-western States in the series of culture element distribution studies being made under the auspices of the University of California was carried out in 1935 by E. W. Gifford (*Univ. California Anthropol. Rec.*, **4**, 1; 1940). The material is largely Athabascan, 13 out of 20 groups belonging to this linguistic family. Of the remainder, Piman was represented by Papago, and four were Puebloan, namely, Shoshonean, Zuñian, Keresan and Tanoan. From analyses of the elements observed it emerges that there is a number of universal elements present in all 20 groups which may be regarded as fundamentals of south-western culture. At least 2 per cent of the 2,990 (or, when thoroughly atomized, 6,000) elements are universal to the groups in the region. The 'qualitative' analysis largely supports current opinion as to the relationship of various groups. For example, the Western Apache stand out as not at all acculturated to Plains culture pattern, while their eastern relatives are increasingly so acculturated the farther east one goes. The Navaho appear much more strongly tinctured with Pueblo traits than do the Apache, yet they have a fair number of specialities which set them off from other Athabascans and south-westerns. The Puebloan groups have an extensive common foundation of unique elements. From the statistical analysis of A. L. Kroeber it would appear that the Puebloans form a well set-off group in spite of their internal speech diversity, their closest external relation being Zuñi-Navaho, with Hopi-Navaho next and Tanoan-Jicarilla third. Of the four Athabascan groups, Navaho, Western Apache and Jicarilla constitute cultural sub-groups of some historic depth. The Navaho are far from uniform internally, and eastern and western differ more from one another than any of the five Western Apache who form a closely knit group. The Jicarilla resemble Eastern Apache more than they resemble Western or Navaho. The Eastern Apache are an artificial group; while Papago and Southern Ute fail to show strong similarities with either Pueblo or Athabascan and, therefore, are not "South-western".

Physiological Aspects of Lactation

At the present time, when milk is an article of diet so much in the public eye, the review of the various physiological aspects of lactation by S. J. Folley (*Biol. Rev.*, **15**; 1940) has an added interest. In it the author epitomizes the work that has been done to date on different mammals on this subject, from the endocrine, nervous and biochemical points of view, and, of course, provides an extensive bibliography. In most species œstrogens stimulate the growth of the ducts, but in the guinea pig and goat they also produce alveolar development. In some species growths of both ducts and alveoli are influenced by androgens. The anterior pituitary plays an important part in various activities connected with lactation, and some workers believe that it produces a specific lactogenic hormone. The adrenal-cortical hormone is also essential for lactation, since the removal of the cortex results in the cessation of this activity. There are no true secretory nerves, though the extirpation of the sympathetics disturbs lactation. Lactose is synthesized from blood glucose, milk fat derives from the neutral fat of the blood; but it is improbable that the milk proteins are produced from the amino-acids in the blood. Caseinogen is probably built up from the plasma proteins.

Chromosome Studies

The discovery of the banded giant chromosomes in the cells of the salivary glands of some, but not all, of the Diptera provided a new starting-place for various types of cytological research. T. S. Painter (*J. Roy. Micro. Soc.*, **40**; 1940) has reviewed the results to date from the points of view of the structure of the chromosomes themselves, experimentation upon them by physico-chemical means, and their utilization in hybrids, geographical races and closely related species to estimate what part is played by differences in gene alignment in the formation of races and new species. The bands are made of chromomeres, generally vesiculate, connected by pro tein strands. The chromosomes represent completely uncoiled prophase chromosomes which have undergone a number of longitudinal divisions producing a multiple strand, a polytene. This condition is actually one of polyploidy in which the chromosome strands remain permanently associated instead of forming separate units. Polyploid nuclei with polytenes have been demonstrated in the cells of the mid- and hind-gut of mosquito larvæ and pupæ and in other parts of other insects. Their large size and the constancy of the band pattern have permitted the experimental deletion of relatively limited regions and in this way a localization of certain genes to a definite band. In species allied but with the same chromosome number, realignments of the bands are found.

A Giant Hydroid

THE giant among hydroid polyps is undoubtedly the Japanese deep sea form, *Branchiocerianthus imperator*, one of the Corynorphidæ, with a length of 2,235 mm. Recently, another hydroid has been discovered in shallow water off the Argentine Islands by the British Graham Land expedition, which, while only 850 mm. long, is easily the next in size. It is *Myriothela penola*, and is fully described together with another new species of the genus, *M. capensis*, from East London, South Africa, where it was collected by Prof. Stephenson and Miss Eyre, in a paper by S. M. Manton (British Graham Land Exped., Sci. Rep., 1; 1940). This, the second largest hydroid, belongs to the Myriothelidæ, and one of the differences between it and the largest is that in *M. penola* there is no hydrocaulus, so that the length is all body, whereas in *B. imperator* the bulk of the animal is hydrocaulus and the actual hydroid body is only about 40 mm. It is probable that the large size in these two not closely related animals is attained by continuous growth from recognizable growth-zones and a consequent absence of specific size. *M. capensis* is by comparison only a midget, for it measures 17 mm. In spite of this enormous difference of size, the nematocysts are only a little smaller in the smaller species and are of the same four types. Those of the British *M. cocksi* are intermediate in size, being, like the animal itself, slightly larger than in *M. capensis*. Both new species are bisexual. In *M. penola* transportation of the enteric fluid is brought about by ciliated grooves lying between the close-set villi of the blastostyle, and binucleate cells, only rarely met with in the animal kingdom, occur in the endoderm.

Variation in Fossils

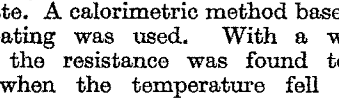
MUCH excellent work has been done in studying the variation in fossils belonging to a single assembly of more or less contemporaneous individuals. But there is a more important problem, namely, to compare closely allied assemblages belonging to different generations, and so to assess the part played by variation in evolution. This is the principal subject of the presidential address delivered on March 13, 1940, by Prof. H. H. Swinnerton to the Geological Society of London (*Quart. J. Geol. Soc. Lond.*, 77, 96; 1940), and he explained some methods he had devised for this problem. The usual method of comparing one fossil with another by eye is too much dependent on the personal element. For measurements upon single features, or two features of which one is expressed as a percentage of the other, the usual statistical frequency curves can be used. The real difficulty arises when three components are considered. Scatter diagrams were used by Day and afterwards applied very extensively by Trueman; but if we try to compare one scatter diagram with another, as is necessary in comparing an ancestral community with a community derived from it, we get an almost hopelessly confused mass of dots. Prof. Swinnerton's method is to draw a polygon (the 'scatter periphery'), and to draw two 'median lines', one parallel to each co-ordinate axis, each of which divides the number of dots into two equal parts. We may also draw the 'limiting frame', that is, the smallest rectangle with sides parallel to the co-ordinate axes which encloses the scatter periphery. Superposition of two such scatter peripheries, with the accompanying median lines and possibly the limiting frames, enables one to make a rapid comparison of two assemblies, and to draw certain general conclusions. The large proportion of comparable combinations which each descendant assemblage has in common with the ancestral assemblage becomes apparent, and the remarkable stability of the communal heritage.

High-Frequency Resistance of Superconducting Tin

IN the issue of the *Proceedings of the Royal Society*, A, of November 27, 1940, H. London reports experiments carried out in Oxford and Bristol on the high-frequency resistance of tin in the superconducting state. A calorimetric method based on eddy-current heating was used. With a wave-length 20·5 cm., the resistance was found to decrease *gradually* when the temperature fell below the transition point instead of showing the characteristic *sudden* drop in resistance to direct currents. Good agreement between experiment and theory, based upon the simultaneous presence of normal and superconducting electrons, was found. Absolute measurements of the conductivity in the normal state at low temperatures with both high and low frequencies showed that, at the temperature of liquid helium, the conductivity for high frequency is considerably lower than for low frequency. In explanation, it is suggested that the mean free path of the electrons becomes larger than the penetration depth due to skin effect under the conditions of high conductivity and high frequency.

Synthesis of Cannabinol

IT has been suggested that cannabinol, a constituent of the resin of *Cannabis indica* first isolated in 1896, is 6″-hydroxy-2 : 2 : 5′-trimethyl-4″-*n*-amyl-dibenzopyran:



and this has now been confirmed by R. Ghosh, A. R. Todd and S. Wilkinson (*J. Chem. Soc.*, 1393; 1940) by synthesis. In this, 6″-acetoxy-2 : 2 : 5′-trimethyl-4″-*n*-amyl-3′ : 4′ : 5′ : 6′-tetrahydro-dibenzopyran was dehydrogenated with palladized charcoal, and the almost colourless resin, with the composition stated, was found to be identical with cannabinol, a constituent of Indian and Egyptian hashish. This was confirmed by comparison of its acetate and *p*-nitrobenzoate with the corresponding esters of the natural material.

POWER AND COMBUSTION

PROF. A. C. G. EGERTON delivered the twenty-seventh Thomas Hawksley Lecture of the Institution of Mechanical Engineers on November 15 last. At the outset, he emphasized the fact that the sun is the source of practically all power on earth. Its surface (photosphere) has a brightness temperature of 6,000° C., and radiates energy at the rate of $3 \cdot 8 \times 10^{33}$ ergs per second. This radiant energy works a great engine of $2 \cdot 3 \times 10^{14}$ h.p. wherein the sun is the furnace, the atmosphere is both working substance and cylinder, and space the condenser. Within the workings of this engine potential energy is being converted to kinetic; kinetic back into potential. Approximately 35 per cent of the energy of radiation is used in evaporating waters of the ocean and the land. On condensation the energy is released: some returns as kinetic energy of the rain or the rivers; some appears in the wind and thunderstorms.

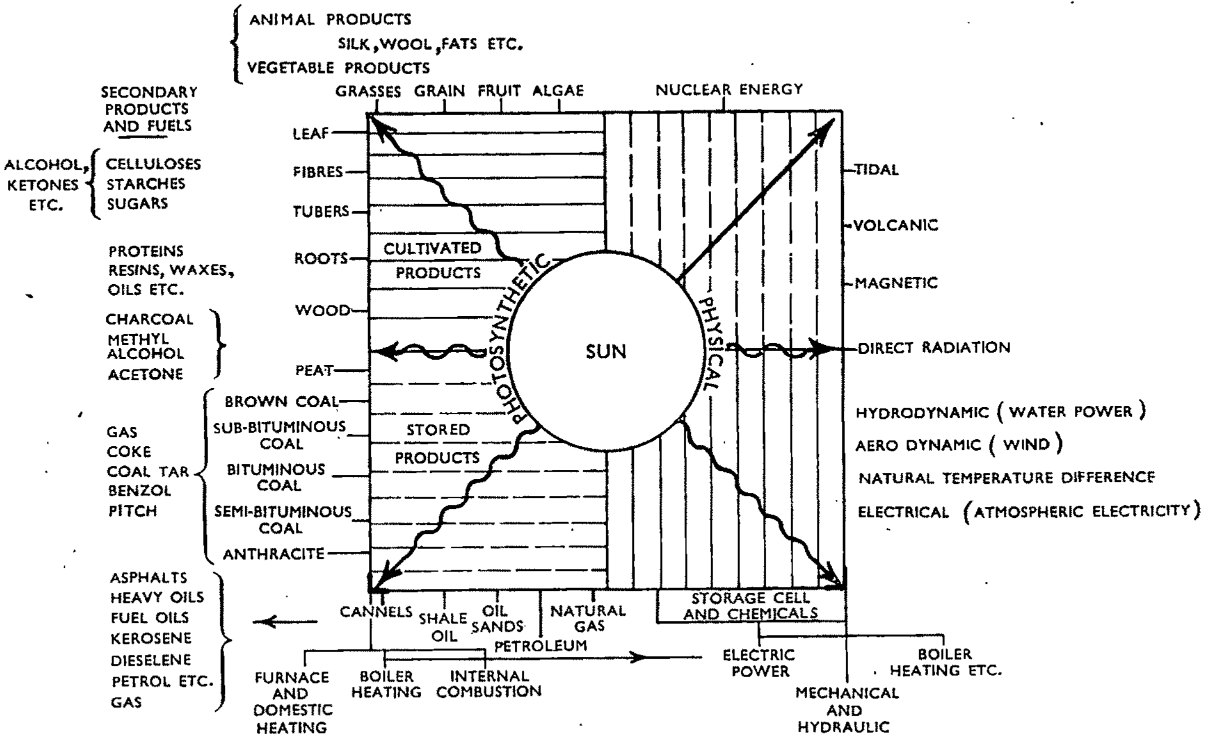


Fig. 1. [*By courtesy of the Institution of Mechanical Engineers*

Tidal power, which is mainly derived from the gravitational effect of the mass of the moon, also falls within the whole scheme of solar energy, for the moon was born of the earth. Volcanic power represents the energy remaining of that with which the earth was originally endowed by the sun and is maintained by the sun's radiant energy, which prevents further cooling. Atomic energy, or the conversion of the matter of the earth into energy, is now an enormous source of potential power, and should it become available as a result of the artificial fission of uranium, it will also represent part of the energy derived from the sun, since the earth was born of the sun. Energy might also in theory be derived from any region where differences of temperature are maintained by natural means; for example, the lower and upper layers of tropical seas. The energy of lightning might be harnessed, but its total contribution throughout the world would be small.

At this point in his lecture Prof. Egerton examined the nature of power and pointed out that there are two kinds: the power that drives, and the power that directs. Human beings are able to direct the activities of Nature and thus obtain power from the effects of the sun on the atmosphere. There is, however, another factor which is capable of directing power, and that is plant life. Photosynthesis takes place within the cells of the plant as the result of the utilization of radiant energy falling on its surfaces. The products of photosynthesis are valuable sources of power. The origin of coal is certainly vegetable, and the origin of oil is, according to the author, almost certainly mainly vegetable.

Fig. 1 serves to summarize the various sources of power discussed by Prof. Egerton. The section shaded with broken vertical lines indicates physical sources dependent on solar radiation and utilized mainly by means of hydro-electric stations. The section shaded with full horizontal lines refers to the products of photosynthesis. The section shaded with broken horizontal lines indicates those products which have gradually been stored throughout geological time.

The two main sources of power are hydro-electric power and power from stored fuel. The latter has the advantage that the energy can be transported where it is needed.

After an admitted digression which included discussion of some interesting problems of combustion, ignition of hydrocarbons, 'knock' and treatment of petroleum, Prof. Egerton returned to the main theme of his lecture and summarized conclusions reached by means of a diagram of human activities (Fig. 2). Starting from the centre, solar radiation provides stored and cultivated products. The energy value of the foods produced would be less than a tenth of the fuel produced, but the gold value of the foodstuffs is far greater than the value of all other production. Food provides energy for the worker, and fuels supplement his work. In this way the energy is as it were 'up-graded' in order that exchange may be made for food. In the process of keeping the mechanism of the body in action, food energy is 'down-graded'. Waste in either the 'up-grading' or 'down-grading' process should not be tolerated if the best use is to be made of radiant energy. Other essentials of life besides food and water include clothing, shelter, warmth and rest. Some of these are obtained through fuels, others through treatment of agricultural products. Sometimes the agricultural product is broken down; sometimes it is preferable to build up from the fuel.

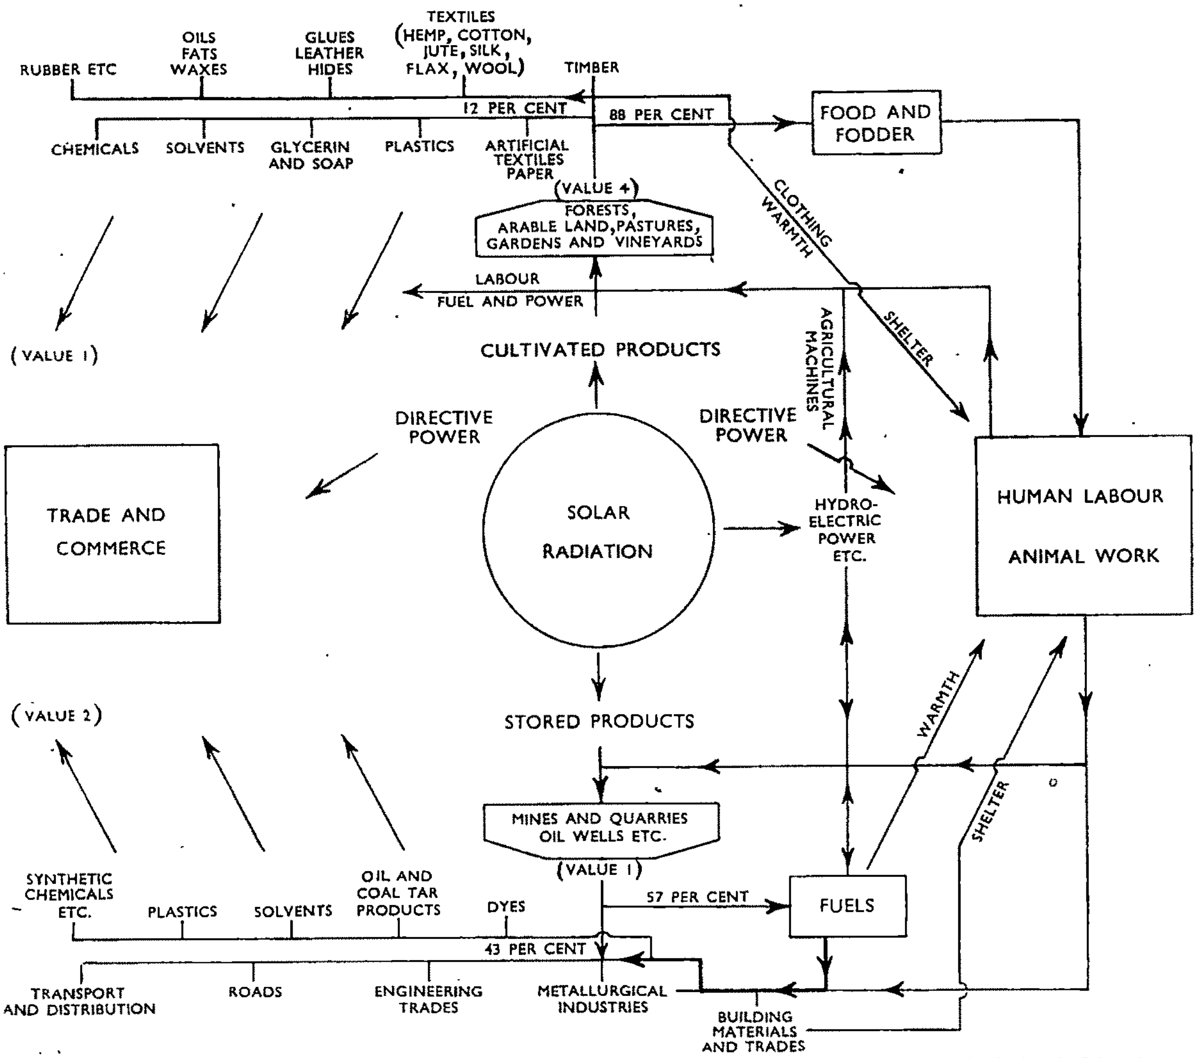

Fig 2. [*By courtesy of the Institution of Mechanical Engineers*

In conclusion, Prof. Egerton suggested that some control should be exercised over primary fuels and over wheat, which is the key food. In this way the riches of the earth would not be squandered and the material economy of the earth might be run far more smoothly. He also suggested that as much power as possible should be derived from the solar energy which is continuously being showered upon the earth (60,000 times as much as the energy at present being used) rather than from inherited stores. In other words, a greater distinction should be drawn between the use of real irreplaceable capital and replaceable products which the sun provides on the earth.

POPULATION INCREASE IN NEW YORK STATE

FOLLOWING up two previous studies of recent changes in the population of New York State, W. A. Anderson now examines the natural increase in that population (Cornell Univ. Agricultural Experiment Station, *Bull.* **733**, 1940). 'Natural increase' is here measured through an index in which the number of children less than five years of age per 1,000 women aged 20–44 years is divided by a replacement ratio, this ratio being the number of children less than five years of age per 1,000 women, aged 20–44, in the stationary population which would result from the continual operation of the current mortality-rates and in the absence of any migration.

Replacement ratios as of 1930 have been computed by the Scripps Foundation for Research in Population Problems, as follows: New York State 442, Urban 443, Rural 439. Are the populations in the various areas of the State reproducing at these rates? New York State as a whole with an index of natural reproduction of 88, which is 12 points below the necessary, is not reproducing itself, while it is decidedly deficient as compared with the native population of the United States as a whole, which is reproducing at the rate of 112. The urban population of the State has an index of 84 (U.S.A. 86), but the index of the rural population is 120 (U.S.A. 154), that of the farm population being 139 and the non-farm 113. Thus the urban population is not replacing its losses, and inasmuch as 87 per cent of the women of 20–44 reside in urban areas, the urban type of population influences the natural increase of the State most significantly, being about four times as important as the rural population in determining the total natural increase.

Several important social implications result from these facts: If the population remains constant or increases, migration both from without and within the State will be considerable. If mobility within the State increases, this normally being after adolescence, important issues as to the finance and adequacy of education arise, affecting also the standing of churches and other social organizations. The question whether the excess population is being produced by the class most fitted economically, socially, and educationally requires special study, though it has been suggested that it is derived from those least fitted to reproduce at the higher rates.

FORTHCOMING EVENTS

ECONOMIC POLICY AND MAN-POWER

THE need for a comprehensive and coherent policy covering the whole of the economic field has repeatedly been pressed upon the Government, with little apparent effect. One cause of the misgivings often expressed lies in the upward trend of prices, encouraged by the disparity between the purchasing power poured into the market by Government expenditure and the fall in supplies inseparable from war conditions, resulting in some commodities being beyond the reach of families not engaged in any munitions industry, apart from the many whose incomes have fallen off or who have become unemployed. The Purchase Tax itself has given a further impetus to raising the cost of living, and the increase in railway charges has given a sharp reminder of dangers attending the absence of any consistent policy for the control of wages, costs, and prices. Moreover, there has been no indication of the methods by which the Government proposes to prevent the dislocation and anomalies which are bound to attend the increasing deflection of non-essential industries to war purposes if businesses and individuals affected are left to adjust themselves to the new conditions without guidance and assistance. We have no evidence of any plan for collective action by industries to enable them to switch into direct war work the maximum of man-power and equipment with the minimum of friction and economic waste, or of any wide extension of rationing and price-fixing to ensure fair distribution of the reduced quantities of goods available.

The greatest single cause of misgiving is the persistence of unemployment on a relatively large scale. Most economists agree that these figures clearly indicate that the war machine is failing to absorb labour as quickly as the civilian industries are releasing it. Misgivings publicly expressed by such authorities as Prof. Pigou cannot be lightly dismissed, and while leadership admittedly can achieve better results than dictation, such leadership must possess a definite aim and a clear understanding of the means of attaining it.

It is the absence of the prompt and firm use of such powers to remove difficulties before they become really serious which indicates the lack of an adequate central economic plan. Mr. Bevin's general references to an enormous call-up for the Services and for munitions industries between now and next June, coupled with the absence of measures to facilitate even the transfer to munitions work or the armed Forces of the 75,000-100,000 workers which Mr. Greenwood has estimated would be liberated by curtailment of home production between now and May, are indeed somewhat disturbing. The balance between industrial workers and combatants is delicate, and to be determined with the fullest circumspection. The war will be won by mechanisms, not by vast masses of men, and our limited population cannot multiply combatants and the mechanized weapons they require at the same time.

Apart from this difficult question, there is the balance between the distribution of skilled labour not only in the munitions industry so as to ensure the maximum use of all available labour, skilled and unskilled, but also with reference to the demands of the armed Forces, shipbuilding, and the like, for technicians.

Not merely man-power, but the whole of our economic resources, whether production of munitions or foodstuffs, import and export policy, rationing of food or other essential commodities, and restrictions of manufacture and on means of transport or shipping, must fall into the proper place as part of a single economic plan intimately related to the strategy and plan of campaign of the Fighting Services. Above all, this plan must be conceived in an offensive and not purely a defensive spirit, and by minds alert to the creative possibilities of new ideas and new measures.

The recent Cabinet reorganization announced by the Government may be regarded as in some measure a reply to such criticisms. It is, however, difficult at first sight to believe that the re-casting of the machinery thus announced will effect much more co-ordination or eliminate the dangerous amount of free fighting between departments. Mr. Churchill has himself assumed responsibility for ensuring that the work of the Production and Import Executives corresponds to the general policy of the War Cabinet, but we are still without any minister, backed by an adequate selected general staff, to handle the whole field of economic affairs.

The new Import and Production Executive Committees which replace the previous councils, although of much the same departmental composition, will possess executive powers, and their work, as well as that of the three existing committees on civil defence, home policy, and food policy, will be concerted and directed by a committee on which the chairmen of all these bodies sit, under the chairmanship of the Lord President of the Council. This committee will advise the Cabinet generally on the movement of business in the executive committees and on special questions remitted to it. It will also deal with the general issues of economic policy formerly considered by the Economic Policy Committee.

The official announcement expresses the hope that these arrangements will bring the very complicated affairs of government in war-time into a simpler and more closely knit structure, with a reduction in the number of subsidiary committees and the promotion of rapid and decisive action, while preserving the constitutional responsibilities of ministers to the Crown and Parliament. Such a system of committees, however, can scarcely be viewed without misgivings by students of scientific management. *Prima facie*, it appears to disregard the fundamental principles of organization and the span of command, and to place upon the committee system a burden which that useful aid to management should not be expected to shoulder.

Mr. Churchill devoted some part of his speech in the House of Commons on January 22 to a defence and explanation of these arrangements. In spite of a spirited defence of the committee system, the Prime Minister scarcely met the real point of the criticism, and uneasiness as to the persistence of departmentalism was not dispelled, willing as all may be to judge the system by its results. It is, after all, the evidence as to the lack of a general and coherent plan that has stimulated criticism of the machinery of government in the first instance, and the report of Lord Haldane's Committee on the Machinery of Government may yet supply pertinent reading after more than twenty years' neglect.

Although dissatisfaction with the Government's labour and economic policy is freely expressed, it should not be imagined that shortcomings are only to be found on the Government side. There is little enough evidence in Mr. John Price's "Organized Labour in the War", published last autumn in the Penguin series, of a wider vision or sense of unity.

What the Government must recognize is that public opinion fully realizes that our economic and man-power resources, great as they are, are definitely limited, and we can no longer afford to tolerate limitation of output, reluctance to transfer to urgent work because of inconvenient travelling, or opposition to the introduction of trainees. The greatest impatience, indeed, with Government policy arises out of what is felt to be the excessive dependence of ministers upon appeals to the public in matters where they have, at their own request, been given power to take whatever action may be necessary. We can carry our servience to the voluntary principle to a point at which the very cause of freedom is endangered.

Ready as the public may be to accept the use of the compulsory powers with which the Minister of Labour and National Service, for example, has been endowed, it does not follow that the first steps need be taken in his own immediate domain. There must undoubtedly be swifter executive action in dealing with industrial treachery, but the mobility of the national labour force may well be increased indirectly by such means as compulsory billeting for transferred workers, or adequate attention to welfare work. These, with an overhaul of the present priorities system and the careful handling of the extended training programmes and of the effective utilization of the firms engaged in the non-essential industries with their resources in man-power, capital equipment, and business organization, should go far to keep compulsion to a minimum, provided it is clear that the Government will not hesitate to use its powers if necessary.

The industrial registration plan outlined by Mr. Bevin at the beginning of the debate on man-power and production in the House of Commons on January 21, by which it is hoped that all reserves of labour will be mobilized for war work, promises the development of a more scientific policy, although critics in the debate pressed for stronger action. None the less, Mr. Bevin could point to certain measures which had been or were being taken to improve the immediate situation, as in repair and turnover of shipping, and his subsequent statement after his conference with the General Council of the Trades Union Congress and the Council of the British Employers' Confederation should go some way to dispel fears that the Ministry will be lacking in firmness where voluntary measures may fail or prove inadequate.

The paper on "Some Problems of War-time Labour Management", which Dr. K. G. Fenelon gave before the Royal Society of Arts last autumn, illustrates how important a contribution to the conservation and efficient utilization of our man-power resources can be made by wise management. Here, as in the new machinery announced by the Government, it is largely a question of personalities. Men and not machinery will decide whether or not the new War Executive is capable of winning the War.

Co-ordination is, of course, at bottom, the ordinary work of administration. Co-ordination of plans and performance is a condition of the day-to-day working and management of any business or industrial undertaking, and when difficulties arise it is more often that lack of a policy and a programme are the root cause, rather than lack of co-ordination.

What is required now is action, not merely plans, and if Mr. Churchill's reshuffle leads to sovereignty and authority in economic policy and not mere machinery, it may open the way to that gathering momentum in production and ruthless common sense in trade and distribution on which alone victory can be based. Effective action must, none the less, be dictated by a coherent plan taking account of all our resources of man-power and materials, eliminating all sources of waste, and determining the size of our Army, not independently, but in relation to the resources available to meet the needs of the Navy, shipbuilding, and the merchant navy, the requirements of the Air Force, the various branches of Civil Defence, and the demands of food production and transport.

THE WORLD IN UNITY AND STRUGGLE

Dialectics of Nature
By Frederick Engels. Translated and edited by Clemens Dutt. Pp. xvi+383. (London: Lawrence and Wishart, Ltd., 1940.) 15*s*. net.

FREDERICK ENGELS died in 1895, one year before Röntgen's discovery of X-rays and the enormous flowering of physical and chemical knowledge that followed from it. Science to-day is very different from what it was in his time, and the appearance for the first time in English of his main theoretical work, "Dialectics of Nature", may seem a matter only of historical curiosity. We might wonder, indeed, why at this late date it is worth bringing to light at all instead of relegating it to the forgetfulness that has fallen on the theoretical works of even the greatest of the Victorians.

The question can only be answered by picking up the book. "Dialectics of Nature" has a different quality; it does not belong to the normal stream of Victorian thought. Had it appeared at the time it was written, a great majority of scientific workers would not have read it, and those who did would have considered it to be ridiculous philosophic nonsense. That was because Engels did not consider science in any narrow framework; he saw it always as part of a general movement of human and universal history. He had a comprehensiveness of view that appeals to us much more now than it did to his contemporaries. Two trends, one inside science and one in the world of human affairs, have brought us nearer to appreciation of Engels' meaning. The progress of scientific ideas: relativity, the quantum theory, the development of biochemistry and genetics, have added immensely to our understanding of Nature, but they have provided not only knowledge but also deeper problems and difficulties—difficulties that were not visible in the classical scientific world picture which rested on Newtonian mechanics and Darwinian evolution. Engels' main concern is just with those fundamental difficulties; on the relation of matter and movement, on the nature of cause and effect, on the irreversible historic aspects linking the inorganic and the organic worlds.

But science does not proceed in a vacuum. It is not only the world of thought but the world of action that has been transformed and has shown both the enormous growth of human power and the problems and struggles which the social utilization of that power has engendered. Physically as well as intellectually, we are in a far less secure world than our grandparents, and it is in this world of struggle that the ideas of Engels, and of his great companion in arms, Marx, have found their most convincing expression. To the Victorian mind freedom broadened down from precedent to precedent, war became a barbaric anachronism, and ever-increasing prosperity followed inevitably from the proper understanding of eternal economic laws. Marx and Engels were the first to point out that this apparent calm development concealed the most violent conflicts and that these conflicts were not likely to be resolved in any continuous way, but in a series of ever-increasing economic, political, and military crises.

The new way of looking at science comes, therefore, both from within and from without the field of scientific study. The value of the "Dialectics of Nature" is that it is the first sketch of that new view. It is not in fact more than a sketch. Apart from a masterly introduction which sums up the historic and economic view of scientific thought, and three or four chapters devoted to mechanics and physics, we have merely disconnected notes for a book that was never written. But what they lose in order and finish of presentation, they gain in freshness. We have here the immediate impact of Engels' mind on the scientific problems of the day, and we get from it, as Prof. Haldane points out in the preface, an invaluable impression of how to tackle fundamental scientific problems in a new way. To read Engels at all requires abandonment of the fixed prejudices, dear to the traditional English men of science, that science is non-political and non-philosophic. Engels will have none of these limitations and he says why :

> "Natural scientists believe that they free themselves from philosophy by ignoring it or abusing it. They cannot, however, make any headway without thought, and for thought they need thought determinations. But they take these categories unreflectingly from the common consciousness of so-called educated persons, which is dominated by the relics of long obsolete philosophies, or from the little bit of philosophy compulsorily listened to at the university (which is not only fragmentary, but also a medley of views of people belonging to the most varied and usually the worst schools), or from uncritical and unsystematic reading of philosophical writings of all kinds. Hence they are no less in bondage to philosophy, but unfortunately in most cases to the worst philosophy, and those who abuse philosophy most are slaves to precisely the worst vulgarized relics of the worst philosophers." (pp. 183–84.)

The philosophy that Engels introduces into science is derived from that of Hegel, but it bases itself, thanks to Marx's intuition, on the actual world of matter and history, and does not claim an abstract priority of pure thought. This Hegelian origin has been enough to turn many scientific workers, even those most sympathetic to the results of Marxist analyses, such as Prof. Hogben, against their philosophic bases. But actually, as Engels has pointed out, the leading ideas are neither very complex nor paradoxical—they are almost commonplaces ; the value of stating them is that of making them conscious and no longer implicit. For convenience they have been reduced to a small number of phrases, such as the negation of the negation, or the transformation of quantity into quality, but these phrases are merely labels for aspects of material transformations which can be grasped only through their examples, and such examples are given very fully in the "Dialectics of Nature". The fundamental concepts are on one hand the historic unity of the universe in its transition from cosmic chaos to human society on the surface of a minor planet ; and on the other the continual series of struggles and interactions by which are brought about the sequence of transformations that mark off different stages in that development. The sciences of physics, chemistry, biology, and sociology are seen as a hierarchy, not only of complexity but also of time. Each is dependent on the coming into existence of its field of organization. The jumps between one field and the next, as between physics and chemistry, or chemistry and biology, are determined by the conditions operating in the prior field. To resort to an external causal agent is to beg the question ; as Engels wrote, "God = Nescio". The primary condition for the appearance of a new stage is the lack of balance in the older one, a failure in the equilibrium of contrary tendencies. These tendencies are apparent at every stage.

Engels will have nothing to do with special forces, which are merely a means of concealing ignorance. For him everything reduces to matter itself and its forms of motion. At the physical level he considers attraction and repulsion as the characteristic opposite forms of motion. They are not, however, simple motions to and from a point. They correspond rather to potential and kinetic energy of the system. However much they may change places, they never cancel each other out. The modern atom in its half quantum ground state would have been exactly the kind of thing that would have appealed to his imaginative understanding. In another way he was also surprisingly modern; he refers to atoms themselves and molecules not as fixed unalterable units but as nodal points in a series of movements and transformations.

It is, however, in his approach to biology and sociology, where the material is more tractable without the need for the mass attack of the physical laboratory, that Engels' ideas seem more positively fruitful even to-day. His views on the origin of life and its necessary dependency on the pre-formation of complex carbon compounds—"life is the mode of motion of proteins"—is still in advance of that held by many biologists and scientific philosophers of to-day. In organic evolution he was shrewd enough to see that the simple Darwinian picture is too crude a translation of the ethics of free competition into the biological sphere. Here change comes from the struggle, not so much between individuals or species, as between the linked opposites of heredity and adaptation. The inherent tendencies of the organism which embody its history are as relevant as the environmental changes.

With man, as Engels says, we enter history. The characteristic human attributes are to him no longer individual but primarily social. Work, in the sense of activity conditioned by the group, is here the differentiating factor between man and animals:

> "The normal existence of animals is given by the conditions in which they live and to which they adapt themselves—those of man, as soon as he differentiates himself from the animal in the narrower sense, have as yet never been present, and are only to be elaborated by the ensuing historical development. Man is the sole animal capable of working his way out of the merely animal state—his normal state is one appropriate to his consciousness, *one to be created by himself.*" (p. 187.)

If anyone chooses to look at the "Dialectics of Nature" as a final statement of a philosophy of science, and expect from it any immediate addition to positive scientific knowledge, he probably will put it down as obsolete rubbish. But if he does this, he will miss its chief value and the object for which it was written—not to tell people about the world, but to point out how they can look at it and how they can change it. J. D. Bernal.

SONS OF CAMBRIDGE

Alumni Cantabrigiensis

A Biographical List of all known Students, Graduates and Holders of Office at the University of Cambridge, from the Earliest Times to 1900. Compiled by Dr. J. A. Venn. Part 2: From 1752 to 1900. Vol. 1: Abbey—Challis. Pp. xii + 550. (Cambridge: At the University Press, 1940.) 150*s.* net.

The University of Cambridge is deeply indebted to the president of Queens' and his colleagues for the devoted labour with which they have brought so near to completion the great task begun by Dr. Venn and his father thirty years ago. It is a testimony to the value attached to the work by the Syndics of the Press that the volume under review, the first of six dealing with the period 1752–1900, should have been published in the present troublous times.

A comparison of this volume with its predecessors shows naturally that fuller details are known of the individual's career both at the University and in later life than in the more remote periods; something of the romance of the earlier history has perhaps vanished with the years: the old class of student with a career in the learned professions or in public life remains, but new elements have entered, which are making their own contribution to the life of their epoch. The country squire has become the county councillor; new careers like the Indian Civil Service open up; students arrive from the Dominions or India: Jagadis Chandra Bose typified a class of students, unknown in the earlier days, coming from the Far East to study at Cambridge, while Wallis Budge and Thomas Arnold represented the class that went to the Far East to excavate and investigate the great civilizations of the past.

The past tense is used in the preceding sentence because it is not intended in this notice to refer to living persons, though happily many are still alive whose names appear in the volume. These are not so many as they would have been but for the War of 1914–18, which took its heavy toll of Cambridge men, as is abundantly clear from this volume. G. A. Arbuthnot, an ex-M.P., who served for more than a year in a mine-sweeper and was killed in action as a second lieutenant in the Grenadier Guards, is an example of the men we lost serving their country by sea, land and air. Dr. H. Ackroyd, winner of the Victoria Cross, upheld worthily in 1917 the tradition set up by William Bankes in India in 1858. These men gave their lives for their country—so, too, did statesmen like Arthur Balfour and Henry Campbell Bannerman devote their lives to the service of their fellows.

Edward Bulwer Lytton and Augustine Birrell provide a link between statesmen and literature, which is represented by Samuel Butler and Byron ; on the lighter side we have Calverley, Burnand of *Punch* fame, and Bowen of the Harrow songs. Byron's name suggests the first cricket match between Eton and Harrow, when W. D. Brockman played in Byron's eleven. The careers of many a famous 'blue' in the major sports provide interesting reading ; the older sport of travel figures freely, and B. Armytage provides an early link between Cambridge and the Antarctic, while J. Buchanan, the oceanographer, was on the *Challenger* expedition ; J. L. Burchhardt, the noted traveller, left his Oriental manuscripts to Cambridge because he there received his earliest lessons in Arabic, and E. G. Browne came back from Persia to the University the leading authority on Persian literature. W. W. Cassels of the "Cambridge Seven" and C. F. Andrews represent groups of Cambridge men who travelled to the Far East and other lands on a different type of mission.

Pioneers of many sides of life are to be found, such as J. M. Bacon, an early experimenter with balloons ; William Cecil, the inventor of the internal combustion engine; F. A. Abel, who discovered cordite. The results of their work may be viewed with mixed feelings to-day, but there will be general appreciation of W. F. Broadwood, who made the first grand piano. Music brings to mind Sterndale Bennett, professor of music in the University.

Professors on the scientific side include J. C. Adams, Clifford Allbutt, F. M. Balfour, W. Bateson and A. Cayley : their work needs no description in these columns. Others whose names catch the eye are G. B. Airy, astronomer royal, James Alderson, president of the Royal College of Physicians, Babbage of the calculating machine, 'Beetles' Babington, Dr. Bright of Bright's disease, Ernest Brown and R. C. Carrington, whose names are associated with studies of the moon and sun respectively ; also H. K. Anderson, a great University administrator whose name is rightly linked with the new University library. Among librarians the name of Henry Bradshawe stands out. Cambridge families whose members have served their University and their country with distinction in many walks of life must not be forgotten : the names of Balfour, Benson, Brett, Butler, Buxton, Cavendish and Cecil (of Burghley) may be taken as a representative selection.

There remain for mention a few who live in memory for some less obvious reason. Thus we have R. Anlezark, who would eat a leg of mutton at a sitting ; Richard Budd had a nursemaid Emma, afterwards Lady Hamilton (Nelson's Emma), and a housemaid, afterwards a celebrated actress, Mrs. Powell ; G. F. Burrell brought forward persistently in Parliament a bill to prohibit window-cleaning by females ; Dr. Barnardo was the famous friend of waifs and strays, and we must not omit to mention Oscar Browning, "the O.B.", "absurd, profound and above all human"—no bad epitaph for a university don.

F. J. M. STRATTON.

ELEMENTARY ANIMAL BEHAVIOUR

The Orientation of Animals

Kineses, Taxes and Compass Reactions. By Gottfried S. Fraenkel and Donald L. Gunn. (Monographs on Animal Biology.) Pp. viii+352+10 plates. (Oxford : Clarendon Press ; London : Oxford University Press, 1940.) 21*s*. net.

SINCE Jacques Loeb formulated his tropism theory some fifty years ago, a vast amount of work has been done on the orientation of the lower animals in relation to light and other environmental stimuli. This is well summarized and discussed in the present volume by Drs. Fraenkel and Gunn. In its original form the theory of Loeb cannot be upheld ; a classification of these elementary reactions proposed by Kühn in 1919 has to a large extent taken its place in the minds of those who approach animal behaviour from the physiological point of view. It is to Fraenkel that we owe the first full exposition of Kühn's views published in Great Britain (1931), and to Gunn the revised and modified classification here presented in the first part of the book. He distinguishes between kineses or undirected reactions, taxes or directed reactions, and transverse orientations (to light and gravity). Kineses are subdivided into ortho-kineses and klino-kineses, and taxes into klino-taxes, tropo-taxes, and telo-taxes. In the second part of the book the available data about these reactions are considered under the headings of the different kinds of external factors "which control them"—temperature reactions, gravity reactions, reactions to chemical stimuli and so on. Many of these chapters are exceedingly valuable to the serious student by reason of the wealth of references and the careful exposition of the most modern work on the subject. The book is very well indexed and there is an extensive bibliography.

There is at present much diversity of opinion as to the proper method of approaching the study of animal behaviour. Some hold that a psychological interpretation is necessary, others that a purely physiological treatment will suffice. The authors appear to reject the former alternative as being "anthropomorphic", and to cling to the old Loebian conception of the animal as a mechanism actuated by stimuli. Thus they describe their book as "principally concerned with the way in which the various external factors—light, smells, currents, heat, and so on—operate the living mechanisms and lead to orientation" (p. 3). Yet they admit that the behaviour of a rat in learning a maze "cannot be described otherwise than in terms of memory or purpose, whether they are overtly so or not" (p. 316). Their attitude seems to be that mechanistic interpretations must be pushed as far as they will go, but supplemented by psychological if the facts absolutely demand it. I do not think this is a very satisfactory position, and I doubt very much the value of treating even elementary behaviour in terms of kineses and taxes; it seems to me too *simpliciste* and abiological. To my mind a psychological and biological interpretation is required all through, and I agree with Bierens de Haan (1940) in thinking that these orientation responses are best regarded as instinctive behaviour of a simple kind, biologically significant in relation to the normal environment and the normal needs of the animal, though not consciously purposive. Some approach to this point of view is indicated on p. 190, where it is recognized that light is often a 'token' stimulus, representing something of biological significance. The authors are well aware of the methodological difficulties in the study of animal behaviour and discuss them at some length, though not very conclusively.

E. S. RUSSELL.

TECHNICAL DYNAMICS

Technische Dynamik

Von Prof. C. B. Biezeno und Prof. R. Grammel. Pp. xii+1056. (Berlin: Julius Springer, 1939.) 78 gold marks.

IN introducing the student to technical mechanics either by lectures or text-book it is usual to lay stress on those simplified problems which illustrate the principles. The more difficult problems in the form in which they face the mechanical engineer, even if touched upon, do not receive the detailed consideration which their importance not only warrants but demands. The present book is designed to form a continuation of the introductory course and may be described as a treatise on technical applications of elastomechanics for advanced students.

According to Kirchhoffe's definition, mechanics consists of kinematics, or the study of motion, and of dynamics, or the study of forces. In this sense dynamics can be divided into statics, the geometry of forces and the theory of equilibrium, and into kinetics, the theory of forces not in equilibrium and the relations between force and motion. For example, an oscillation problem is a dynamical one consisting of a statical part, namely, the investigation of certain elastic properties, and a kinetic part, the calculation of the frequencies. The looser current usage takes dynamics as a synonym of kinetics, and while still describing the oscillation problem as dynamical, neglects the statical part, which is often the more difficult if not the more interesting.

The authors use dynamics in the sense defined by Kirchhoff, and have accordingly investigated both the statical and kinetic parts of a variety of problems concerning rods, shafts, rings, springs, plates, shells and their combinations, keeping in view that any such problem is only worth solving when it has a practical application, and can only be described as solved when a detailed solution in numbers is forthcoming without recourse to too prohibitive numerical calculations. It must not be inferred that the book is a wearisome list of numerical results. On the contrary, great emphasis has been laid on methods of solution; in fact a chapter of 100 pages is devoted entirely to such methods. In the applications, solutions are not merely outlined but are given in full as the engineer would have to work them, and with the choice of method which the authors consider to be the best.

The text is divided into four sections: fundamental theory, 225 pages; single parts of mechanisms, 400 pages; the steam turbine, 220 pages; internal combustion engines, 210 pages.

The first section contains an exposition of the mathematical theory of elasticity as applied to isotropic bodies which obey Hooke's law; indeed phenomena outside the elastic limit are not considered in the sequel. This account of the theory is well and carefully written. It is refreshing to see the authors emphasize the strict limitations of the theorem of unique solution of elastic problems, in that in actuality finite (but small) strains and finite (but not small) stresses represent only approximations to the conditions in which the classical equations are valid. A simple illustration is Euler's strut at the first critical load. Another welcome feature is the inclusion of the proof of de Saint Venant's principle based on that given by Zanaboni (*Atti Lincei*, 25 ; 1937). With regard to the general theorems of elasticity it is to be regretted that the authors have not given the vector formulation which makes the physical implications much easier to grasp.

The remaining three sections consist of applications of elasto-mechanical theory with special emphasis on the needs of machine construction. Special prominence is given throughout to critical loads and values.

The authors remark in the preface that the chapters have been arranged so far as possible so that each can be read independently. This has been achieved within limitations, but the text requires close attention on the part of the reader, who is assumed to be proficient in elementary mechanics and to have a fairly extensive knowledge of mathematics.

The book is a mine of detailed information such as could probably not be found in collected form elsewhere (for example there are 89 pages on the loaded rod) and it should therefore prove to be of great value, and, one regrets to add, of great cost. L. M. MILNE-THOMSON.

MODERN DRUG THERAPY

Modern Drugs in General Practice
By Dr. Ethel Browning. Pp. vii + 236. (London : Edward Arnold and Co., 1940.) 10*s*. 6*d*. net.

IT has been said that prontosil with its colourless prototype sulphanilamide are destined to be regarded as one of the greatest boons to mankind conferred by the present age. Having regard to that opinion, which few will dispute, the author is not without justification in devoting one-sixth part of a book on modern drugs to the sulphonamides ; indeed, had it been thought necessary to extend this not-too-long chapter, a few of the eleven pages on gold salts might have been spared, for, admittedly, gold therapy is strictly limited in its applications.

Experience in the treatment of the war-wounds of the civil population during the past few months, and even the past few weeks, has added to our knowledge of the richness and even the shortcomings of the sulphonamides, which, of course, can only be recorded in current literature, but nevertheless can be the more readily appreciated against a background such as Dr. Browning has provided. Another topical chapter is the one concerning external applications and local anæsthetics ; again, in this connexion, much has been learnt, in recent months, in the grim school of experience ; much is still being learnt.

When this book was commenced, and even when the labour was over, it was generally believed that tannic acid was the dressing *par excellence* for burns, but in the past few weeks it has been shown that there are pitfalls in its way, and that in no circumstances should tannic acid preparations be used on burns of the hands or face. It should be noted that Dr. Browning puts it on record that gentian violet has been found in many cases more efficacious than tannic acid as a remedy for burns, especially when combined with other antiseptic dyes, and mentions that a successful method for severe and extensive burns is to combine gentian violet, brilliant green and acriflavine as a 'three-dye' mixture which forms a stable solution, relieves pain, forms an eschar, thinner but more flexible than that formed by tannic acid, and obviates the preliminary cleaning-up which is so painful and likely to increase shock in cases of extensive burning. Incidentally, a jelly containing gentian violet and merthiolate (sodium ethylmercurithiosalicylate) was recently substituted for tannic-acid jelly as a first-aid application in the Navy and Royal Air Force.

Nearly half the chapter on cardiac drugs is devoted to the digitalis group ; digitalis, although it has been known to medicine for centuries, is not out of place in a treatise on modern drugs if only for the reason that its glucosidal derivatives, as, for example, digitoxin, digoxin, digalen, and so on, which have to some extent replaced in clinical practice the older galenical preparations, are of comparatively recent introduction. Other chapters deal helpfully with drugs acting on the autonomic nervous system, diuretic and urinary antiseptics, and sedatives and hypnotics. The "easy availability" of the barbiturates, referred to in the pages dealing with sedatives and hypnotics, is no longer a ground for objection to the valuable drugs in this group, since the Poison Rules prohibit their use except under medical supervision.

MENTAL HEALTH IN WAR-TIME*

BY SIR WALTER LANGDON-BROWN

IF there is one thing which is certain about the outbreak of wars, it is that the ostensible reason is not the real one. Emotional causes are always transformed into ones alleged to be rational. We know that when a quarrel blazes up between two individuals over a trivial matter, there are deep-seated and hidden causes of antagonism at work. In the same way, no one to-day believes the shooting of an archduke by an insignificant conspirator was the real cause of a war which devastated a large part of the globe for more than four years and cost millions of lives. The cause lay deeper.

Sir Flinders Petrie, in his delightful little book, "The Revolutions of Civilization", maintains that each civilization goes through a cycle, waxing, flourishing and waning in turn. He plotted this out in curves, based on certain recurring features in each civilization. Now the interesting point is that, whether one agrees or disagrees with his views, in this book published in 1911, his curve for the present civilization cut the base line in about 1914. In my Maudsley lecture for 1936 I directed attention to Sir Arthur Keith's dictum that there are two opposing tendencies in life—one the general demand for the enlargement of the social unit—the other the species-making impulse which attempts to segregate a particular type. I ventured to point out that in human life the first makes for internationalism, the second for nationalism. The fierce fanatical outbreak of nationalism which this century has witnessed becomes comprehensible as a frightened response of the species-making segregating impulse against the imperious, resistless demand of the ever-widening evolutionary process towards internationalism.

Now amid all the differences between schools of psychology, there is general agreement on this point—if a normal healthy impulse is forcibly repressed it is apt to come to the surface again in an abnormal pathological form. If this evolutionary demand comes into opposition with a nation that is at once convinced that its culture is the only one really worth having, and is filled with the spirit of aggression, the result is not difficult to predict; and though that spirit of aggression was temporarily checked, the consequences to civilization proved more serious than was realized at the time of the Armistice in 1918.

We now see that the years 1918–1939 were but a troubled armistice between two wars, during which the building up of vertical walls between nations was countered by horizontal lines of cleavage, which threatened to divide Europe into Fascists and Communists. This to my mind represented the pathological form of internationalism resulting from repression of its normal expression. The well-intentioned League of Nations was quite inadequate to deal with the resulting situation. Then extremes met in the Russo-German pact which indicated a new orientation, the division now being between those nations which considered that the individual existed for the State, even though "the State" meant a few autocrats, and those which thought the State existed for the individual. Meanwhile, amid these pathological manifestations an internationalism was arising, and one which seems to us normal and healthy, in the free association of nations within our own dominions. Since the military, political and moral collapse of France, the United States has been thrown into closer relations with that association, and there are clear indications that this process is likely to extend.

This, then, seems to me the background against which the present War is being waged; a moral and spiritual disease in Europe as the result of attempts to stem the tide of the evolutionary process. Also we can admit that on our side the idea of liberty has been too negative, and that we have not formulated a positive conception that is sufficiently adequate for the situation.

Let us now turn to the effect of all this on the mental health both of the community and the individual. One is rather tired of the platitude that the child is father to the man, and yet to-day I am forcibly reminded of it. Watch a child playing with his bricks and carefully constructing an elaborate edifice. Then suddenly his mood changes and with a scream of delight he knocks the whole thing over with a sweep of his arm. It makes us realize that from the first both constructive and destructive impulses are present in the human mind and that there appear to be epochs when the destructive one simply runs amok. Such an epoch we are now passing through. Of course this impulse is rationalized, and it is claimed that the old state of affairs was so bad that it had to be destroyed before anything better could take its place. I do not believe that applies to a complex civilization; but, then, I believe in evolution and not in revolution.

The common man wants to be left in peace with his wife and family and carry on his ordinary avocations. Unless those are threatened, only the adventurous want to fight. Therefore it has always been a common device of absolute rulers to distract attention from internal difficulties by telling their peoples that some other nation is trying to deprive them of their heritage. As we are gregarious animals, we close our ranks at a hint of danger. The thrill of alarm brings also a new sense of unity; men cannot bear to feel isolated, and barriers break down. A new spirit of tolerance and good will springs up with a readiness to sacrifice to a common end. All this is to the good, but these earlier effects are not always lasting.

---

* From a Chadwick Public Lecture delivered at the Royal Society of Tropical Medicine and Hygiene on February 4.

Nations at war look instinctively for a leader. Whatever else he does or lacks he must capture the imagination. He must be regarded as a superman, but with some appealing traits. It does not matter if the leader is credited with characteristics he does not possess; the virtues of Kitchener and Hindenburg were great, but not identical with the popular estimate of them.

Prof. Jung must have been prophetically inspired when he said in a lecture in Vienna as long ago as 1932 (and I am only condensing his remarks without adding to them):—

> "Everything could be left as it was if a new way of life were not absolutely demanding to be discovered and was not visiting humanity with all the plagues of Egypt until it is found. Instead of being exposed to wild beasts, tumbling rocks and inundating waters, man is exposed to-day to the elemental forces of his own psyche, and so he seeks with more intensity than ever for personal leadership. This is an indestructible human need, but once tradition has been sufficiently lopped off by the revolutionary, unhistorical and therefore uneducated inclinations of the new generation, leadership is the more fanatically defended the more unsuitable it is."

Leadership, then, is a necessity, and as in so many aspects of war mentality, the emotional predominates over the intellectual assessment of the value of the leader. From the South African War onwards I have been struck with the 'writing-up' of leading generals, obviously to inspire confidence in them, a confidence which in several instances was proved by subsequent events to have been misplaced. A leader who can both arouse emotion and appeal to reason is indeed an asset—and we believe that we have such a one.

In ancient times the supremacy of the emotional over the rational attitude expressed itself in consultation of augurs and omens and of ritual observances before going to war, as an attempt to allay inner anxiety and guilt. When war comes, each side firmly and fiercely denies its responsibility, however obvious the facts may be. Indeed, the guilty party is usually the more vociferous in its denials because deep down it feels the truth of the indictment. Then in times of national anxiety there is a regression to certain primitive mental traits. This was well illustrated in Germany by the ritual of driving nails into the gigantic wooden image of Hindenburg, a totem figure of the tribe. A commoner tendency is the making of myths—an escape from reality into fantasy. In the early days of the War of 1914–18, the myths of the angels at Mons, and of the Russian troops passing through England, were widely believed. War had seemed incredible, and these consequences seemed no more incredible. This time war has been threatening for so long that there was not the suitable atmosphere for the propagation of such naïve myths, and people have more sense of reality now. Local rumours exaggerating the damage done by air raids have, however, been abundant. Curiously enough, spreading bad news appeals to vanity. Where facts are few, rumours are rife. The best cure for rumour is information. From the frequency with which Virgil refers to rumour, we may surmise that the Romans were plagued by it. Rumour, he said, "has a hundred tongues, a hundred mouths, a voice of iron". Again, "Rumour, than which no evil thing of any kind is more swift, increases with travel and gains strength by its progress." Since then a swifter method of spreading false reports has been bestowed on the world by science in wireless. Thereby the power of the lie has been enormously enhanced. Truth seems to be a very plodding tortoise compared with the racing hare of lies.

Now all those traits—the demand for leadership good or bad, the reliance on myth and rumour—arise from the same cause; as gregarious animals we are always suggestible, and never more so than when we are in danger. As Mr. Wilfred Trotter pointed out, the physical dependence of the infant develops later into suggestibility which is psychic dependence, a necessary pre-requisite of group life and activity. The dependence of infantile life thus develops into the inter-dependence of social and communal life. It was the greatest weakness of Thomas Hobbes' philosophy that he tried to deal with man as a separate unit—*in vacuo*, as it were. This is impossible. The right course is to canalize this inevitable suggestibility, heightened as it is in war-time, into co-operation.

The greatest enemy to be overcome is fear. For years insidious propaganda has skilfully instilled fear like a creeping poison until, as we have seen, nation after nation has just waited its turn like a rabbit paralysed by terror at the stealthy approach of the stoat that will presently seize it by the throat. It may well be that this could never have happened if at the very moment when nationalism seemed at its very height, there had not been a subconscious feeling that nationalism itself would prove to have been decaying at the roots. It is worth while, then, to inquire into the genesis of fear. It is the survival, and sometimes the perversion, of a defensive mechanism of great antiquity and real value; alertness in the presence of danger, by which the whole organism is keyed up, ready for action. It is activated through the sympathetic nervous system, which prepares the body for fight or flight. But if action be prevented, the same mechanism produces fright. Then, as Crile puts it, we become like motor-cars with the clutch thrown out; petrol is consumed, and the whole car may tremble from the violent action of the engine, but the car does not move. This is the scientific explanation of the fact that the best corrective of fear is action.

Psychologists tell us that an unconscious persistence of an infantile sense of guilt is a large element in exciting fear. That may be so, but it does not help when the sirens sound; there is no time then to be analysed and have our infantile fantasies exorcised! A distressing form of fear is that which comes from being afraid of being frightened. This is clearly due to a conflict between two powerful instincts—the instinct of self-preservation and the herd instinct, which strongly condemns what seems like cowardice. Action as a member of a community, especially if under suitable leadership, is the best antidote.

Dr. W. R. Bion, who has recently written helpfully on community feeling in war-time, considers that the civilian is at a disadvantage compared with the soldier, in that he has not had the disciplinary training. The soldier can form a tolerably accurate picture drawn from experience of similar conditions; the novice tends to be flooded with emotions which he cannot check by appeal to facts. There is even a chance that the aggressive component of these emotions will be directed towards his own side rather than towards the enemy.

The soldier is a member of a close unit expressly designed for facing tasks which involve the possibility of death, whereas the civilian has no really powerful check to his natural desire for self-preservation and may be isolated in a way which causes a loss of social sense. The strain will be diminished for those civilians who are serving in some organization which has definite clear-cut aims, with powerful emotional appeals and a discipline. It is necessary to find some modification of the disciplinary framework that exists in a fighting service and to adapt its organization to the needs of the civil population.

Dr. Bion quotes from Tacitus a description of the conduct of the German tribes warring against the Roman troops of the Emperor Trajan—of the way that they inflamed their minds with barbarous poetry (in a hymn of hate), the furious uproar, their uncouth and harsh vociferation, interrupted at intervals by the application of their bucklers to their mouths, so that the noises burst out with redoubled force. Students of infant behaviour have noted that the earliest fear a child experiences is that excited by noise, and the Germans, true to their own tradition, have actually added devices to their shells, whereby the screaming noise of them may be still further increased, so as to arouse a primitive type of fear. This could reasonably be countered by the use of ear plugs, which would be both physically and psychologically protective.

We can understand why pessimism and fear are chiefly prevalent among those who are doing nothing, or at any rate not contributing to our war effort.

The best antidote to fear is action; and we need an antidote, for we cannot expect to be entirely free from fear. The Emperor Charles V, seeing on a Spanish nobleman's tomb the epitaph, "He never knew fear", remarked, "Then he never tried to snuff a candle with his fingers!" Sir Philip Sidney expressed the same idea in more serious style when he wrote, "Fear is more pain than is the pain it fears".

The general experience, however, so far, bears out the report of a conference of medical men convened by the Minister of Pensions before the active stage of war began. They stated that a very exaggerated estimate had been formed of the liability of war to produce nervous breakdown. This has been amply substantiated since the intensified air raids on Great Britain have been in progress, and that in spite of all the suffering and loss that have resulted. A writer in the *British Medical Journal* explains this in an interesting way thus: "With the constant threat to the existence of the entire community constituted by repeated and indiscriminate bombing, a superb scapegoat is at hand. . . . The facility with which one can now project one's fears and anxieties is likely to be the most important one" in preventing such breakdowns. "The herding together of individuals in shelters in the face of common danger and the levelling-out process in society which is consequent upon universal hardship have no doubt been essentially responsible. Further, the opportunity for dramatization afforded by narrow escapes, etc., is a decided factor."

During the Spanish Civil War it was found that in Barcelona, a particularly heavily bombed city, nervous breakdowns were neither numerous nor severe. An interesting comment on this was made by a German refugee professor, now in Great Britain, to the effect that in a civil war everyone fanatically takes one side or the other, while in a war between nations the individual is less personally involved. As this professor served in the German army in the War of 1914–18, this view is specially interesting, because if individual Germans felt that way then, it is almost certain they feel more so now. It is also reassuring to have confirmation of our belief that confidence in the justice of a cause is a splendid preventive of nervous breakdowns. That confidence we possess.

The danger underlying herd feeling is panic, for we are suggestible in a wrong as well as a right direction. Therefore anyone who goes about suggesting that an epidemic of nervous breakdown is likely, for which there is really no warrant, is doing what he can to produce panic. In the War of 1914–18 the populace was singularly free from panic, as it is now under much more trying conditions, and it was rather surprising that before Munich there were symptoms of this dangerous response to danger. The intervening eleven months seemed to steady the nerves of the people of Great Britain and to transpose the liability to panic on to some of our administrators.

By what other methods besides co-operative action can we help to preserve mental health in war-time ? Physical fitness undoubtedly helps. I remember in the War of 1914–18 a man telling me that it was his duty every night to take supplies up to the front line, which he did without fear, until one night when he had a severe cold ; on that night he experienced acute fear.

To obtain sufficient sleep is also essential to maintaining physical fitness. Rather than disturbing rest by a flight to a shelter, in many cases it is sufficient to arrange bedrooms on the ground floor or in the basement. I am reminded of the old controversy whether to shelter under a tree in a thunderstorm or not. You have to put the remote prospect of that tree being struck by lightning against the much greater chance of a severe chill from getting soaked. Poincaré, the mathematician, and brother of the politician, said during the air raids on Paris during the War of 1914–18 : "I sleep securely under the shelter of the laws of probability." However, the probabilities are less favourable now than in that war.

It is clear from the report of Lord Horder's Committee that the conditions obtaining in many shelters are not conducive to physical fitness, to put it very mildly. If we are to be condemned to revert to the cave man's existence, there is no reason why we should also revert to his primitive ideas of sanitation.

Cheerful surroundings help to banish fear. The Germans proclaimed a war of nerves months before hostilities began, and they have gained considerable success by the menace of air raids which has necessitated the 'black-out' with its depressing effect. If there must be darkness without, there can be and should be light within. You absorb more from rooms furnished and decorated to your taste than perhaps you imagine. You think you have ceased to notice a charming picture on your walls until it is taken away. Then you miss it at once, which shows it was always exerting its effect, although you were apparently unaware of it. That is where life in shelters is apt to have an evil effect in this war of nerves.

Books are a great solace these dark nights. I am enjoying renewing my acquaintance with that fine English literature of the last century which this restless age has been neglecting to its own disadvantage.

Do not omit to meet your friends, and if rationing compels simpler hospitality, remember that in the eighties of last century this was generally the custom, and we were certainly not less happy. Then there is the radio. Needlework reached artistic heights during the Napoleonic Wars ; the creation of beautiful things always has a cheering influence. If you are feeling too geared up, lie down, close your eyes, breathe deeply and relax all your muscles. Do it for twenty minutes at a time. This is a great help, for you can waste a lot of nervous energy by just uselessly tightening up your muscles if you are feeling frightened. But the main thing to do is to change useless muscular action into some useful activity.

We have reserves of tenacity and endurance, inherited and maintained through generations of stable and equable ancestors. Boswell once said of some behaviour of Dr. Johnson to his College tutor, "That, sir, was great fortitude of mind", to which Johnson replied, "No, sir, stark insensibility." I do not think our national fortitude is based on insensibility. We may well scoff at pretentious and unjustified claims made elsewhere to racial purity. We are the product of the fusion of many tribes, from which something new emerged, differing from its original constituents as much as an amalgam of metals differs from its separate ingredients ; a people liberty-loving, tolerant, humorous but reticent, steadfast but quite unwilling to look unpleasant facts in the face until compelled to do so. Thus, though a peace-loving nation, when we do get roused we become the more fierce precisely because we resent the necessity for it. Just a century ago de Tocqueville said of democratic peoples, "The same passions which made them attach so much importance to the maintenance of peace will be turned to arms. . . . Hence it is that the self-same democratic nations which are so reluctant to engage in hostilities sometimes perform prodigious achievements when they have taken the field."

In the interests of our mental health we must be determined to carry on in the same liberty-loving spirit into the peace, which will have its own special difficulties. Prof. R. B. Mowat, in an interesting article, has pointed out that, from the French Revolution to the Battle of Waterloo, the whole of Europe was in the melting-pot before the impetus of that revolution was exhausted. In the same way it has been again in the melting-pot since 1914, and again we may expect the impetus of this revolution to die down. Then, as before, will come the period of reconstruction. What kind of world will arise depends much on our attitude now—it will decide whether the melting-pot is to be a witch's cauldron or a refiner's fire.

If we are to escape future disasters we must learn more about ourselves and our own nature. The ancient Greeks, and in our time Thomas Hardy, regarded man as the sport of inevitable fate ; the modern psychologist shows us that fate is the outcome of individual and national temperament. The future is ours to redeem, and this can only be achieved by self-knowledge and mutual sympathy. One of the direst aftermaths of war is an inevitable hardening of the boundaries between nations and the withdrawal of feelings towards international sympathies. That is why the League of Nations failed, and why for the present federal union can only remain a dream. Nevertheless, it is an excellent thing to talk about federal union ; it took years of talk to accustom men's minds to something so obviously right as the abolition of slavery.

Yet a more international spirit will have to arise if civilization is to be saved. Isolation in thought and ideals is absurd at the very time when wireless has joined up the whole world and it has become increasingly clear that even material prosperity depends on commerce being international. Peace must mean more than simply the cessation of war ; it must be based on a new spirit of co-operation and we must hope for its emergence from the refiner's fire. H. G. Wells has said that the only chance of ever becoming more reasonable is by realizing how unreasonable we are ; to which one might add—and by trying to understand why we are so unreasonable. Recent events have proved that, under the superficial crust of civilization, the age-long forces of savagery and brute instinct are still alive. To recognize their existence is the first step to canalizing their energy in right directions. "In man's very flesh and bones is the impulse towards closer and closer union in larger and larger fellowship. To-day he is fighting his way towards that goal." The path is difficult and will be fraught with many disappointments as in the past. It was recently remarked that the problem of the future is to combine individual freedom with collective responsibility. On whether we can achieve this or not depends the future of civilization. The world stands at the parting of the ways.

THE OIL/WATER INTERFACE

By Dr. J. H. Schulman,
Department of Colloid Science, Cambridge

A JOINT meeting of the Faraday Society and the Physical Society was held in London on January 9 to discuss the oil/water interface. In spite of adverse conditions which prevail at the moment for such meetings, and the impossibility of the meeting taking on its usual international atmosphere, the room was quickly filled beyond capacity. There were also some of our Dutch, Belgian and Greek colleagues present to keep alive the spirit of international collaboration in science, fostered by the Faraday Society discussions. The discussion, which was opened by the president, Prof. E. K. Rideal, was at times very animated. The president stressed the implications this subject has on a very large number of scientific and industrial fields, and the papers read were divided into biological, physical, chemical (emulsions), and theoretical sections.

The chief aspects dealt with in the papers read were the influence of the chemistry and structure of the interface on the adsorption and diffusion of ions and molecules on to and through the interface and on the kinetics of reactions taking place at the interface; likewise also, the influence the chemistry and structure of the ion or molecule has on the above factors.

Dr. A. E. Alexander (Cambridge) started the discussion by giving a review of the monolayer technique applied to both the air/water and oil/water interfaces, and stressed the use which a combination of the two methods has on elucidating and predicting phenomena occurring at the interfaces. Attention was directed to the fact that surface potential measurements at an oil/water interface can be made if the ionizing air electrode is in the air above, and not if the ionizing electrode is in the oil layer just above the interface. The oil layer has to be of the order of only 1 mm. or 2 mm. in thickness.

The discussion then centred on the fact that at the oil/water or air/water interface the equation of state for substances examined by Alexander and Teorell gave 3/2 KT instead of KT as previously found by Langmuir.

It was pointed out by A. B. D. Cassie and R. C. Palmer (Leeds) in their paper that deriving a surface equation of state for strong electrolyte detergents by a combination of the Poisson, Boltzmann and Gibbs equation gave a factor of 3/2 KT for ionized films as compared with KT for unionized films. They actually used Alexander and Teorell's results to confirm their theoretical deductions. It would appear that the presence of the ionized polar group at the end of the hydrocarbon chain, as compared with an unionized polar group or dipole, is responsible for this 1·5 factor in the equation of state for monolayers at interfaces. A confirmation of this suggestion was considered important.

Dr. G. S. Hartley gave the first demonstration of how simple alterations in the structure of the adsorbing molecule can radically affect interfacial conditions. It is known that the lowering of interfacial tension at the oil/water interface is due to the ions of the paraffin chain salts, and the sudden break in the interfacial tension concentration curve coincides with the formation of micelles.

Hartley reasons, therefore, that by changing the structure of straight single-chain paraffin salt to that of a double-chain salt, two changes in the interfacial tension phenomena curves should take place. First, on changing the configuration of the non-polar portion of the molecule, one alters the adhesion balance of the molecule with the water molecules. Thus, with two chains there would be more accessibility for the water molecule to the hydrocarbon molecule than with one chain; hence the double-chain molecules would have less interfacial activity at identical concentrations. However, since steric factors with the two chains would alter the micelle packing, greater concentrations of the double-chain ions would be required before micelle formation can take place. Thus one should obtain with double-chain molecules a greater lowering of the interfacial tension than with a single-chain molecule containing an equal number of carbon atoms.

This theory is very prettily justified experimentally. Single-chain ions of sixteen carbon atoms, or double-chain ions with one long and one short chain, lower the interfacial tension at low concentrations to a greater extent than double-chain ions of eight carbons each. But at higher concentrations the double-chain ions lower the interfacial tension to much smaller values than the single-chain ions. This fact is well demonstrated by the spontaneous emulsifying properties of sodium dioctyl sulphate (Tergitol) as the agent in an oil-in-water system as compared with sodium cetyl sulphate, showing that there must be a very low interfacial tension of the solution of the double-chain molecules.

A. C. Frazer (London), J. F. Danielli and J. H. Schulman (Cambridge) showed how physical chemical studies of interfacial phenomena can be applied to biological problems.

Frazer has established by a series of direct analogies with artificial systems that the particles which exhibit strong Brownian movement in blood plasma are fat emulsions, stabilized by a protein film around each particle. The particles consequently behave as a protected colloid and have all the physical chemical properties of the adsorbed protein and not of the fat of which they are essentially composed. Furthermore, the protein adsorption is specific, since the particles take on the characteristics of the globulin fraction of the serum. Strong support is given from the monolayer and electrophoretic techniques in establishing the fact that fats adsorb preferentially the globulin fraction of the serum and not the albumen fraction.

Discussion immediately centred around this important result. It was considered unlikely that the fats could participate in this specificity, and it was suggested that it was due to some difference in the chemical constitution of the proteins affecting their hydrophobic – hydrophilic balance. The globulins were supposed to have more CH_2 groups in their side chains than the albumens; but on the other hand the serum globulins are known to associate with lipoid substances specifically in the serum, which may account for their ability to adsorb on to fats, etc.

It has been shown by Frazer that this preferential adsorption of the important serum globulin which is associated with the immunity properties of serum, is given also by toxins (bacterial and snake venom) and hormones such as insulin. The biological activity of these substances is completely inhibited when they are in the adsorbed state. Apparently the phenomenon is reversible since, upon the emulsions being broken, the biological action of these substances returns. This is a very good example of how orientation of a molecule or certain components of the molecule at an interface can radically alter its chemical activity (as exemplified by its biological action). The significance of these results was fully appreciated by the meeting.

J. H. Schulman demonstrated how alterations in the structure and orientation of molecules composing the interface can also radically affect the course of a reaction taking place at the oil/water interface. From direct analogies as to the mutual orientation of the hydrocarbon chains attached to the acid and alcohol radical of an aliphatic ester at an air/water interface, the adsorption of OH′ ions to the interface and the specificity of the digestion of aliphatic esters by ferments can be explained. Thus when the hydrocarbon chains are orientated parallel to one another (*cis* form) leaving unrestricted approach to the polar group from the water phase, adsorption of OH ions can take place together with digestion of the esters by lipoclastic ferments. If the chains are orientated opposite one another (*trans* position) adsorption of OH′ ions is greatly restricted and digestion is completely inhibited. It requires only a 5-carbon atom hydrocarbon chain on the acid radical to bring about complete indigestion of the ester; but 5-carbon atoms on an alcohol radical chain permit the molecule to orientate in the *cis* position and be easily digested. Thus, ethyl valerate is indigestible, but amyl propionate is readily digested by the lipoclastic ferment in pancreatin. The activity of the ferment itself is enhanced by the presence of most paraffin chain salts both positive and negative, except that of the long-chain sulphates, which cause complete inhibition of the ferment action in minute concentrations.

The adsorption of OH′ ions at oil/water interfaces was discussed in some detail following the presentation of results obtained by the school of Prof. W. C. McC. Lewis at Liverpool on the electrophoresis of emulsions or suspensions of oil in water (W. Dickinson and G. Growney).

It was shown that the adsorption varies markedly with a number of factors. In the first place, it varies with the physical nature of the surface, that is, liquid or solid. Discussion took place on the interesting fact that the increase of adsorption of OH ions in alkaline solution on the change from a solid to a liquid is gradual. The melting point gives no marked change. This was explained by the fact that X-ray diagrams of paraffins show no marked change over the melting point. Thus the change in area of the surface molecules in the neighbourhood of the melting point can be considered as changing gradually and not in a sharply defined manner as characterized by the melting point. This also gives an explanation for the apparent anomaly of the adsorption of OH ions on mixtures of ethyl laurate and stearic acid.

Stearic acid alone is a solid, but mixed in small concentrations with ethyl laurate it will give a liquid film of adsorbed stearic acid at the ethyl laurate/water interface. A liquid film of stearic acid will adsorb more OH ions than either a solid film of stearic acid or a liquid film of ethyl laurate.

The adsorption also varies with the stereochemical structure of the oil phase and hydrogen ion concentration. Thus aliphatic long-chain esters fall into three groups: those that are solids which adsorb OH ions poorly; those in which the esters are orientated in the *cis* form, which absorb OH ions gradually with increasing pH, and those in which the esters are presumably orientated in the *trans* form, or in a form which only permits adsorption to take place at pH 9.

Discussion took place as to the reason why the electrophoretic mobility of ester (or other hydrocarbon compounds) suspensions changes with increasing pH until pH 9 is reached, and then remains nearly constant. There is no change in the curve over the region where hydrolysis is known to commence. There was no adequate explanation forthcoming for these interesting facts, which may have some bearing on the mechanism of hydrolysis in general.

J. F. Danielli (Cambridge) gave a theoretical interpretation of interfacial phenomena as related to a living cell. The cell membrane consists (to a first approximation) of a thin oil layer with a protein film adsorbed on its two surfaces. A molecule penetrating through the membrane must penetrate (*a*) the external interface, (*b*) diffuse through the thin oil layer, (*c*) penetrate the internal (cytoplasm-oil) interface. Attempts were made to plan the kinetics of diffusion through this system on a quantitative basis: this problem cannot yet be dealt with accurately owing to lack of a theory of diffusion which is cognizant of the influence of structure on diffusion. Some useful preliminary relationships between oil-water partition coefficients and permeability constants have been obtained, and approximate values calculated for the permeability of a thin oil layer to hydroxylic compounds. It was emphasized that with polar compounds the resistance to free penetration lies largely in the necessity of breaking hydrogen bonds between polar groups and water before penetration of the external oil-water interface can occur, and with non-polar compounds the principal resistance lies in the difficulty experienced by hydrocarbons in diffusing from oil into water.

The problem of emulsions was presented by R. C. Pink (Belfast) and A. King (London). The former pointed out that metallic soaps are poor emulsifiers unless they act as solid stabilizing agents. There are three essential functions attached to a solid stabilizing agent essential for emulsion stability. The agent must be insoluble in both phases, but must be wetted by both phases, and the particles must inter-associate to form a stable interfacial layer. A metallic soap which can be readily dispersed in oil acts as a solid stabilizing agent if the action of water precipitates it out of dispersion; thus magnesium oleate gives excellent water-in-oil emulsions, whereas zinc or nickel oleate give no emulsions.

A. King stressed the importance of the interfacial film on the stability of emulsions in general as measured by the change of area of the interface with time. Emulsions stabilized by agents such as soaps give much finer emulsions than those stabilized by solids such as alumina, but the former are easily influenced by the presence of salts and temperature, whereas the latter are stable against most conditions, such as salts, temperature and *p*H. The effect of salts of the lyotropic series on emulsions stabilized by saponin are interesting. Thus sulphates increase both stability and viscosity, whereas thiocyanates and iodides markedly reduce these properties of the emulsions.

J. Powney and L. J. Wood (London), in conclusion, brought to the attention of the meeting the interesting fact that whereas electrophoretic mobility of droplets and interfacial surface tension both depend on the formation of interfacial films, in a number of cases no correlation apparently exists between the two phenomena. Thus over very small concentrations of the salts of long-chain sulphates and amines, great changes in electrophoretic mobility (of oil droplets) are observed with no measurable change of interfacial tension. Only over the range of concentration where the electrophoretic mobility is nearly constant does the interfacial tension seem to change in any marked degree.

OBITUARIES

Mr. D. Ward Cutler

THE death of Donald Ward Cutler, head of the Microbiological Department at the Rothamsted Experimental Station, came as a sudden and unexpected shock to his colleagues. He had been at his work as usual, then was suddenly struck down with pneumonia and survived only a few days. He was trained in zoology at Cambridge under Prof. Stanley Gardiner, and after his happy and successful undergraduate years at Queens' College he went to the Marine Biological Station at Plymouth to investigate fish scales. In 1915 he joined Prof. S. J. Hickson's staff at Manchester, where his gift for lecturing and for teaching made him a useful member of the department; in his free time he studied the Protozoa of termites. A weak heart prevented his being accepted for active service, but he gave valuable help in the Pathological Department set up for the Manchester war hospitals and became an expert on amœbic dysentery.

After the War he transferred to Rothamsted to take charge of the microbiological work that had for some time been going on there. His first investigations were on the Protozoa of the soil which had been shown to play an active part in the microbiological processes, and he soon succeeded in clearing up many of the difficulties that had arisen in connexion with them. He confirmed Goodey's observation that the ciliates were probably not very active, and Martin and Lewin's observation that the amœbæ were active, and he showed why amœbæ could not easily be picked out from the soil. In conjunction with L. M. Crump he made daily counts of the numbers of bacteria and of certain Protozoa in the soil of one of the Rothamsted fields, carrying on the work without intermission for a whole year, and so obtained a rich mass of data which has since proved very valuable in soil microbiology. The numbers showed considerable fluctuations from day to day, but the bacteria and the Protozoa fluctuated in opposite directions: when the Protozoan numbers were high those of bacteria were low, and vice versa. This accorded with the view that the Protozoa were acting detrimentally on soil bacteria. Later work, however, showed the operation of another factor: in culture solutions the bacteria generally proved to be more efficient when their numbers were low than when they were high, so that the amount of activity per head of bacterial population was actually increased by the action of the Protozoa.

He also studied the bacterial oxidation of ammonia to nitrate, and showed that this is a commoner property than had been supposed.

In recent years his chief work had been on the purification of effluents from sugar beet and milk factories, an investigation carried out at the request of the Department of Scientific and Industrial Research. He was in charge of the microbiological side and the late E. H. Richards of the chemical side, and the good personal relationships of the two leaders enabled them to bring the work to a satisfactory conclusion. During these investigations much valuable information was accumulated about the decomposition of organic matter by bacteria, and this is now being put together.

Ward Cutler's interests, however, were by no means confined to microbiology. He was an active member of the Councils of the Eugenics Society and of the British Social Hygiene Society, and he wrote two well-known books, "Heredity, Evolution and Adaptation" and "Some Problems in Soil Microbiology". He was also a good lecturer, giving generous service to the Workers' Educational Association and other bodies. For many years, too, he was an enthusiastic supporter of amateur theatricals, wherein he displayed no mean ability. Finally, he had an attractive personality and the great gift of winning the loyal support of his staff.

E. J. RUSSELL.

Prof. D. Robertson

WE regret to record the death of Prof. David Robertson on January 8. He was born on December 26, 1875, and like his grandfather, David Robertson, LL.D., the well-known naturalist of Cumbrae, his bent was scientific. Educated at the Hermitage School, Helensburgh, he studied engineering and electricity in the West of Scotland Technical College and the University of Glasgow, where he gained the Sir John Pender Gold Medal, and where he took the degree of B.Sc.(Eng.). Later he was awarded the degree of doctor of science by his own University in recognition of his valuable research work.

After two years as lecturer in the Bradford Technical College, he worked, on original lines, for thirty-eight years in Bristol, where he became professor of electrical engineering in the Merchant Venturers' Technical College in 1902, and in the Faculty of Engineering in the University of Bristol in 1909. He was chairman of the Western Centre of the Institution of Electrical Engineers in 1916, and president of the Bristol Association of Engineers in 1922.

His twenty-seven publications covered a wide field in engineering, and they reflect his character in attention to detail and accurate observation. It makes the achievement of his work so much the greater in that he was confined to an invalid's chair for the last thirty years of his life.

No doubt his works' training in the shops of Messrs. James White, Ltd., was responsible for his great interest in instruments and clocks. "Electrical Meters on Variable Loads" shows the errors which arise under these conditions. "The Clock and Striking Mechanism for the Great Bell of the University of Bristol" gives details of his own design of striking gear, escapement and system of controlling the rate of the clock by means of wireless signals from Greenwich. "The Stroboscope in Speed Measurements and other Engineering Tests" and "The Separation of No-load Stray Losses in Continuous-Current Machines by Stroboscopic Running-Down Method" deal with the principles and application of the stroboscope, and show how the no-load losses can be obtained with accuracy in machines which come to rest in less than one minute. Papers on other subjects include "The Mathematical Design of Transformers", showing how the cheapest transformer for a given output with specified losses is designed; "A Mode of Studying Damped Oscillations by the Aid of Shrinking Vectors", showing in a simple manner how electrical oscillations, or any kind of vibration, can be represented by a vector rotating with uniform angular velocity and, at the same time, shrinking at a uniform rate, so that its path is a spiral.

In recent years he published a very important series of papers on the whirling of shafts and cognate problems. These did much to explain many puzzling phenomena in the running of loaded shafts, and have received high commendation from the special workers in that field. They are notable in the ingenuity displayed in devising experimental methods, and for the criticism of previous work, much of which was mathematical.

S. HOLMES.

Mr. J. A. Tomkins

WE regret to announce the death of Mr. John Arthur Tomkins. He was born in 1874, and received his early education in London. From the age of fifteen he was apprenticed to a firm of scientific instrument makers, with whom he was connected for many years. Between 1892 and 1898, he attended Birkbeck College and the Royal College of Science, of which he became an associate. At this point he entered the teaching profession at West Ham Technical College, as a lecturer in mathematics and physics, and finally joined the staff of the Bradford Technical College in 1903. There he remained until his retirement in 1939. At Bradford, where he became in fact, if not in recognized status, the head of both the Physics and Applied Optics Departments, his long service has left a lasting memorial.

The skill and knowledge acquired in his youth as an instrument maker went with him during life, and Bradford Technical College is enriched with a number of soundly designed instruments. Tomkins' own interests lay perhaps more in the direction of applied optics than pure physics, and many of his thirty contributions to scientific and technical journals dealt with this side of his work. Such a steady stream of published work from a man overburdened with teaching for so many years, actively working for professional organizations (he had much to do with introducing the Association of Teachers in Technical Institutions into the College), and at the same time administering a double department, is its own tribute to his energy and ability. His outside interests appear to have been few, apart from his membership of the Physical Society and the Institute of Physics, of which he was a founder fellow. Bradford has lost a devoted servant, and the Technical College is severed from one whose thoroughness, strict devotion to duty, and too modest personality were a part of it for nearly forty years.

J. P. ANDREWS.

WE regret to announce the following deaths:

Father G. Alfani, the well-known Italian seismologist, aged sixty-four.

Prof. P. Broemser, professor of physiology in, and rector of, the University of Munich, formerly professor of physiology in the University of Basle, aged fifty-four.

Prof. W. Bulloch, F.R.S., emeritus professor of bacteriology in the University of London, aged seventy-two.

Mr. S. H. Hamer, C.B.E., secretary during 1911–34 of the National Trust for Places of Historic Interest or Natural Beauty, on February 6.

Prof. R. von Ostertag, formerly director of the Veterinary Department of the German Ministry of Health and of the Veterinary High School, Berlin.

Prof. Vittorio Patti, director of the Rizzoli Institute and professor of orthopædic surgery in the University of Bologna.

Dr. Cresswell Shearer, F.R.S., formerly University lecturer in embryology, Cambridge, on February 7.

NEWS AND VIEWS

Lord Moyne: New Colonial Secretary

THE announcement of Lord Moyne's appointment as H.M. Secretary of State for the Colonies in succession to the late Lord Lloyd will be welcome to all who have at heart the future of the populations of Britain's colonial dependencies. His experience both in and out of office when as the Hon. Walter Edward Guinness he sat in the House of Commons, and his first-hand acquaintance with colonial problems, will secure that even the nation's supreme war effort will not be allowed completely to obscure the claims of the populations, and more especially the backward populations, of Britain's colonial dependencies, nor the measures which have already been initiated for raising the standards of living and health to fall entirely into abeyance, however difficult that task may be. It will be remembered that not only was Lord Moyne head of the financial mission which visited Kenya in 1932, but he was also chairman of the Royal Commission which investigated conditions in the West Indies in 1938. It was on the publication of the report of this Commission and largely in consequence of its findings that the Government initiated its present policy of colonial development through liberal grants from the Imperial Exchequer over a period of years. Lord Moyne's first-hand acquaintance with the problems of backward peoples is not, however, limited to his official relations with them. He has travelled extensively in remoter parts of the world, and the ethnographical objects collected by him, more especially in New Guinea, have added valuable material to the national collections in the Ethnographical Galleries of the British Museum.

Geological Survey of Eire: New Director

MR. D. W. BISHOPP has been appointed director of the Geological Survey of Eire. He received his training in the Geology Department of the Imperial College of Science and Technology, London, and graduated A.R.S.M. in mining geology in 1923. Developing observations made during his field training in Norway, he published his first paper, one dealing with the Sulitelma pyrite deposits, in the *Transactions of the Institute of Mining and Metallurgy*, and in 1924 was awarded the Institute's Student's Prize. He has had wide experience as a mining geologist, having served with the Mazapil Copper Co., Mexico, the African Manganese Co., Gold Coast, etc. In 1928, he was appointed geological curator in the Rhodesian Museum at Bulawayo, and in 1936 he proceeded to British Guiana as Government economic geologist. His publications have dealt with the mineral deposits of Norway, Mexico and especially British Guiana. The appointment of Mr. Bishopp foreshadows a thorough investigation of the mineral possibilities of Eire.

Cyrene: Birthplace of Eratosthenes, 276–196 B.C.

THE advance of the Imperial armies to Cyrene recalls the time when that city was a home of learning and the capital of Pentapolis, a tract of country containing the five cities Cyrene, Arsinde, Berenice, Ptolemais (or Barce) and Appolonia. Cyrene was the birthplace of several learned men, among whom was Eratosthenes, the geometer and mathematician. A personal friend of Archimedes, Eratosthenes was educated at Alexandria and Athens, and for the greater part of his life was in charge of the University library at Alexandria. He was, says Ball, the Admirable Crichton of his age. He constructed instruments which were used for centuries at the University of Alexandria, suggested the calendar in which every fourth year contains 366 days, determined the obliquity of the ecliptic, measured the length of a degree on the earth's surface and attempted to determine the circumference of the earth. In old age he lost his sight, and starved himself to death at the age of eighty-two.

Early Exploration of Kent's Cavern

THE REVEREND JOHN MACENERY, foremost of the early explorers of Kent's Cavern, was born at Limerick in 1797 and was chaplain to the Cary family at Tor Abbey, Torquay, where he died on February 18, 1841. His stone monument is in the cemetery of the Parish Church of Torre, and it states "he inspired respect as a scholar by the vigor of his understanding, his polished taste and varied learning". He made his first visit to Kent's Cavern in the summer of 1825 by chancing to hear a friend express his intention of joining an exploring party there which eventually numbered about a dozen; he made the last of the train, the others spread themselves about but added nothing to what was already known of the cavern, and he betook himself alone to a spot which seemed to have been disturbed. He tumbled it over and found the first fossil teeth he had ever seen; he pursued his search in silence and kept his good fortune to himself, as he "was anxious to send them in the state they were found to Oxford", probably to Prof. Buckland who later in the year visited Kent's Cavern with MacEnery. On that occasion the latter found the tooth of a rhinoceros and a flint blade which he believed was the first ever found in the Cavern.

MacEnery evidently intended to publish his work as he issued a paper as follows: "Shortly will be published, in one volume Quarto, Cavern Researches; or Discoveries of Organic Remains, etc., etc.", but it is likely that he was dissuaded from pursuing the matter as he might come up against ecclesiastical authority. His most interesting finds were the teeth of Machairodus (sabre-tooth) of which he found about eight specimens. These were the first ever found in Britain and were much prized. He also gathered thousands of specimens of the usual cave fauna as well as flints. Unfortunately, after MacEnery's death the whole of his collections were dispersed by auction, and as the Torquay Natural History Society was founded three years after that date there was no local effort made to keep all his treasures in Torquay, with the result that most of them were purchased by the British Museum and only a few are now in the local museum built by the Society.

Great headway was made between 1865 and 1880, when a very careful exploration of Kent's Cavern was made by a committee of the British Association in which Mr. William Pengelly took the leading part. This resulted in the collection of a very large number of specimens which after supplying the Torquay Museum allowed for the distribution of cave material to many other museums in Britain. The finding of another Machairodus tooth by Pengelly was very satisfactory as there had been some who doubted that MacEnery's had come from Kent's Cavern. Pengelly, by his finding Chellean and other flints, was also instrumental in backing up many of MacEnery's surmises and theories. During the winter of 1925 a Committee of the Torquay Natural History Society was formed to work with a Committee of the British Association for carrying on explorations at the Cavern, and in 1926 a commencement was made at a point selected by the late Prof. Sollas; work has been going on each winter since then up to the present year. In one chamber a depth of thirty-four feet of cave earth has been reached and many fine specimens of flints, teeth and bones have been met with; but the name of MacEnery, the pioneer, is never forgotten.

The American Public and Natural History

ALTHOUGH some aspects of museum activity fail to interest the modern public, the enormous influence of the American Natural History Museum, New York, is cited by Charles Russell in its journal, *Natural History* (Dec. 1940). Statistics show the Museum has: 2,000,000 annual visitors, including its Planetarium; 25,000,000 contacts by its Department of Education; 624,000,000 hour-listening to its radio programmes; 1,000,000 learners taught by its education staff; 200,000 miles a year travelled by museum trucks making 40,000 deliveries to schools, hospitals, prisons, colleges and universities; 480,000 visitors to Bear Mountain trailside museums; 35,000 orders for loan materials outside New York, and 27,000 subscribers to its journal. "The real work of the Museum," states Russell, "is to help people become more aware of themselves and of their surroundings, to help them think in terms of realities, not theories."

When the director of the Museum, Dr. Roy Chapman Andrews, writes a popular animal story about a domestic cat, and the assistant curator of vertebrate palæontology, Edwin H. Colbert, can write an equally engaging story about the sabre-tooth tiger, as is done here, science makes enormous strides in educating the public in palatable, yet truthful, biology. Under "Portrait of a Mammalogist" is given the career of H. E. Anthony, who since 1911 has travelled 200,000 miles collecting for the museum exhibits; the department of mammals, of which he is curator, controls nine of the Institution's twenty-eight exhibition halls with approximately 150,000 specimens. His work on South America's early fossil mammals has been particularly conspicuous and tends to substantiate the theory that up to about 600 million years ago the northern and southern continents were joined by a land bridge even broader than the present central American corridor. American museums seem to be unhampered by that unscientific worship of tradition and the past which leaves many of the smaller British museums without any very useful function in present times.

Life-cycle of Wilson's Petrel

IT is seldom that knowledge of a life-history which has baffled observation for sixty years has been completed so thoroughly as in Brian Robert's account of Wilson's petrel, *Oceanites oceanicus* (British Graham Land Expedition, *Sci. Rep.*, 1, No. 2, 1940). Three seasons observations at a locality easily accessible and easily worked from the northern base-hut in the Argentine Islands, afforded material for a full description of breeding habits and development, and comparison of populations on different island groups has led to the recognition of four sub-species. These populations show no plumage distinctions and differ only in the mean of their measurements, the birds becoming progressively larger in higher latitudes. Incubation is shared by both sexes, which take alternate spells of about 48 hours, and hatching takes place in about six weeks. Thermograph records of the temperature within a burrow during incubation and the growth of the nestling show great steadiness, independent of the variations of the outside atmosphere. Mortality of chicks is high, about 65 per cent succumbing, most often on account of starvation due to the blocking of the burrows by snow. The migrations of Wilson's petrel are among the longest known, for these Antarctic-born birds visit the British Isles and Newfoundland, the Red Sea and Persian Gulf, New Guinea and Northern Peru; and yet ringing of individuals has shown that they return each year to the same mate and the same burrow in the Antarctic. During migration between May and October a complete moult of plumage takes place. Many other matters of interest are dealt with in this valuable monograph.

Scenic Aspects of the Weather

WE are indebted to Mr. L. C. W. Bonacina for an illuminating essay upon a difficult subject written at a time when researches in pure knowledge are of necessity few ("The Place of Scenery in the Study of the Weather and Climate". By L. C. W. Bonacina. *Q. J. Roy. Met. Soc.*, 64, No. 287, October 1940). It must not, however, be supposed that this class of work—and especially examples which have to do with feeling as well as thought—are unimportant at the present moment. On the contrary, it is very desirable that contemplative intercourse with Nature should be cultivated during the exasperating experiences of war. Moreover, when we look ahead to the years that will follow the cessation of the present conflict, we see with certainty that the financial restrictions of the times to come can be countered to a considerable extent by concentration on those refined pleasures of the mind and senses which the æsthetics of scenery provide. The present paper is important for its treatment of scenery as a subject in which all the senses (not only the sense of sight) are concerned; and also for the detailed description of particular incidents in which the author observed those charms which landscape owes to certain transient, but recurrent, aspects of the weather.

Electrical Development in Iraq

THE series of articles dealing with various export markets of the world appearing in the *Electrician* includes one dealing with electrical development in Iraq (*Electrician*, December 6). For the last twenty years this has been mainly concerned with the provision of small generating plants designed to supply power and light to firms and for highways. Until seven years ago there was no sign of any intensive activity, but from 1933, development has taken place in Bagdad, Basra and Mosul. For all intents and purposes, Bagdad is the trading centre of the country, but since the extension of the Turco-Syria railways to the Iraqi frontier at Tel-Kotchek, Mosul is tending to develop an independent commercial life of its own. Incidentally, this extension of the railway, in late 1936, is playing a most useful part in the development of a hitherto minor market. At the moment, however, this line is not completed, so that it is not yet necessary for travelling agents to visit Mosul, nor is it necessary to appoint separate agents for this district. It is possible, none the less, that both these steps will have to be taken as soon as the railway is in full operation.

The growth of electricity in Iraq is reflected in the trade returns for electrical machinery and apparatus. For 1935 the total value of imports under this head was £141,846; in 1936 they showed a value of £198,391, and in 1937 a slight drop to £189,972. The figures for 1938 rose again to produce a total of £242,322. Of these figures Germany supplied £11,495 in 1935, £17,294 in 1936, £25,683 in 1937, and £31,795 in 1938. The shares falling to United Kingdom manufacturers over the same period were £103,289, £132,918, £106,525 and £130,859 respectively. Competition has been particularly strong from Germany in the case of heavy oil engines as the prime movers for generating sets. Here Germany had increased the lead she had gained in the years 1936–38. Analysing the figures shows that in dynamos and motors the supply is mainly from the United Kingdom. In 1937 imports in this class were valued at: United Kingdom £15,199, and Germany £4,218. The battery and accumulator market is shared fairly evenly between the United States and Great Britain. During 1937, imports valued at more than £6000 were supplied by both the United States of America and Great Britain. Imports of electric cables were valued at £25,872, and of this the United Kingdom supplied a total value of £19,584. As regards the development of the country, it is important to note that fuel oil is sold at a very cheap rate, about 2*d*. per gallon, and naturally this is the main source of power. With the exception of turbo-alternator sets in Bagdad, the prime movers for generating sets are oil-burning engines.

War-Time Building

THE design and erection of a war-time building present a number of problems which do not arise in times of peace. These are dealt with in *War-time Building Bulletin* No. 10, just issued by the Department of Scientific and Industrial Research (H.M. Stationery Office. 1*s*.). Since a building erected in war-time is presumably important in the war effort, the following factors over-ride almost every other consideration: (*a*) concealment from the air; (*b*) the minimizing of damage due to aerial bombardment; and (*c*) economy in the use of materials. The bulletin explains, in one document, how to begin tackling these problems.

Olinthus Gilbert Gregory, F.R.S. (1774–1841)

ON February 2 the centenary occurred of the death of Olinthus Gilbert Gregory, who for many years held the chair of mathematics at the Royal Military Academy, Woolwich, and was one of the promoters of the University of London, now University College. He was born on January 29, 1774, at Yaxley, Huntingdonshire, and he owed his first knowledge of mathematics to the Leicestershire botanist and agricultural writer, Richard Weston. At the age of nineteen he published a volume of "Lessons Astronomical and Philosophical", and about the same time, like many of his contemporaries, contributed to the "Ladies' Diary", an almanac and serial collection of mathematical papers, commenced in 1704 by John Tipper, and, like all almanacs, published by the Stationers' Company. His writings brought him to the notice of Charles Hutton, the professor of mathematics at Woolwich, and after a few years spent in teaching, bookselling, and newspaper editing at Cambridge, in 1802 he became a master at the Royal Military Academy, and five years later, on Hutton's retirement, he was made professor, holding his chair for thirty-one years.

Gregory was known as an excellent teacher, and he wrote works on astronomy, mechanics, and trigonometry, translated Haüy's "Natural Philosophy", and from 1802 until 1819 edited the "Gentleman's Diary"—founded in 1741—and the "Ladies' Diary" from 1819 until 1840. In 1823 he experimentally determined the velocity of sound. When, in 1827, the foundation stone of the University of London was laid, his was one of the names inscribed on it. His son, Sir Charles Hutton Gregory (1817–98), a distinguished railway engineer, in 1867 served as president of the Institution of Civil Engineers.

The Royal Military Academy

Apart from the universities and Gresham College, the Royal Military Academy is perhaps the oldest of our institutions, with a long line of notable mathematicians. Woolwich became a naval station as long ago as the time of Henry VIII, and in the reign of Charles II a military depot was established there. In 1741, two hundred years ago, the Academy was founded for the education of cadets, with the German mathematician, John Muller (1699–1784), as headmaster. Two years later, Thomas Simpson (1710–61), who had taught mathematics while working as a weaver in Spitalfields and had published a work on fluxions, was made the professor of mathematics, holding that position until his death. He was a fellow of the Royal Society and a member of the Academy of Sciences, Stockholm. Like Gregory, he edited the "Ladies' Diary", as also did Charles Hutton (1737–1823), the self-taught Newcastle schoolmaster who was appointed to the mathematical chair in 1773. Hutton published many valuable works, and became Copley medallist and foreign secretary of the Royal Society. During the professorships of Hutton and Gregory the staff included for longer or shorter periods John Bonnycastle (1750?–1824), the Rev. Lewis Evans (1755–1827), and his son, Thomas Simpson Evans (1777–1818), and Peter Barlow (1776–1862), who from an obscure mercantile situation raised himself to the front rank of physical investigators. Since the days of these worthies of the eighteenth and early nineteenth centuries, the Royal Military Academy has had among its professors of mathematics many distinguished men, including Samuel Hunter Christie and Sir George Greenhill.

Alexis-Marie Rochon (1741–1817)

Among the less well known of the remarkable group of French men of science who lived through the Revolutionary period was Alexis-Marie Rochon, astronomer, physicist and mechanician, who was born at Brest on February 21, 1741, and died on April 5, 1817. Three years before his death, in August 1814, when Napoleon was an exile in Elba and Wellington was the British ambassador in Paris, Brewster, then aged thirty-two, visited Rochon in Paris, and in his diary for August 22 recorded, "I went this morning to call upon M. Rochon... a venerable and intelligent old man of seventy-three, who is well known to philosophers by his scientific works and inventions. He showed me his prismatic micrometer, a small instrument, with a level for measuring the inclination of lines to the horizon by the coincidence of two images, and his method of doubling the double refraction of Iceland crystal by extinguishing two of the images and employing two that are most remote. . . ."

Brewster and Rochon had much to talk about in optics, but optics was only one of the subjects to which Rochon had made contributions. He had been astronomer-optician to the Marine, had made voyages to Morocco and the Indian Ocean, at Brest he had been librarian to the Royal Marine Academy, keeper of a cabinet of philosophical instruments, the head of a workshop and the first director of the observatory founded at his suggestion. He had made improvements in telescopes, in the wire gauze used in ships' lanterns, and had written on the distillation of sea-water and many other subjects. A member of the old Royal Academy of Sciences, suppressed in 1793, he had been given a seat in 1795 in the newly founded National Institute, and had had a share in the introduction of the new weights and measures, and coinage. When after a long and useful career he died, his seat in the Institute passed to Fourier, and his *éloge* was pronounced by Delambre.

Announcements

Sir Arthur Keith has been elected an honorary member of the New York Academy of Sciences.

Dr. A. B. Walkom, secretary of the Linnean Society of New South Wales, has been appointed director of the Australian Museum.

Canada is setting up a blood "bank" to provide transfusions for 20,000 military and civilian casualties.

The New South Wales Health Department proposes to appeal for at least 10,000 residents of both sexes between the ages of eighteen and sixty to participate in a blood-transfusion scheme to provide a twenty-four-hour service of blood donors to hospitals and doctors and a supply of blood for transfusions in any emergency.

According to the Director of the Census, the population of the United States has increased by 8,634,835 since ten years ago, and is now 131,409,881. This increase is the smallest for any decade since 1790 when the first census was taken. It represents a 7 per cent increase in the population as compared with one of 16·1 per cent between 1920 and 1930, and one of 14·9 per cent between 1910 and 1920. The reasons given for this falling off are (1) a decline in the birth-rate and (2) the virtual stoppage of immigration.

The following appointments in the Colonial Service have recently been made: J. Gordon, assistant conservator of forests, Gold Coast; R. G. Morgan, assistant conservator of forests, Gold Coast; T. I. Rees, assistant conservator of forests, Nigeria; Dr. H. F. Birch, assistant agricultural chemist, Jamaica; M. Park (plant pathologist), divisional and research staff officer, Ceylon.

In Nature of February 1, p. 144, the *Athenæum* was mentioned with the *Gardeners' Chronicle* and *Punch* as having been founded in 1841. This is incorrect. The *Athenæum* was founded in 1828, and Wentworth Dilke, one of the group concerned with establishing the other two journals, was editor during the period 1830–46.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Cultural Significance of Science

IN a communication printed in NATURE of January 25, p. 119, Prof. Polanyi takes issue with an earlier leading article[1] which had urged the rejection of the view that "science is set apart from all other social interests as if it possessed a peculiar holiness". A peculiar holiness, he maintained, is exactly what science does possess. The issue has the appearance of being a fundamental one, since it goes to the root of the whole relation between science and the social order, and some measure of agreement about the nature of this relationship is widely considered to be an urgent need. It may therefore be worth while to point out that this particular example of disagreement seems to be based on a purely verbal ambiguity. In the editorial, "holiness" meant, surely, "having an esoteric character", whereas to Prof. Polanyi it clearly meant "having overwhelming ethical value". I, for one, and there are certainly many like me, would not agree for a moment to deny the ethical value of the scientific method; but also do not feel quite confident against the accusation that it has in the main been applied to an unduly narrow range of phenomena. Have we too often exerted ourselves to take an unbiased view of something which is so recondite that there is no adequate reason why the ordinary man should have any view of it, biased or not?

"Scientific detachment", writes Prof. Polanyi, "is of the same character as the independence of the witness, of the jury, of the judge". But the witness, the jury and the judge turn their attention to problems presented to them as being socially important; they are not at liberty to choose to spend the afternoon discussing the sexual habits of Polynesian worms, or whatever else takes their fancy. The Editors of NATURE were, as I understood them, inviting us to spend more time investigating subjects as banal but relevant as crimes. Doubtless it is not altogether easy to preserve scientific detachment in such matters; and one can expect that what are generically termed "powerful interests" will attempt to influence scientific statements on matters of social consequence. But Prof. Polanyi's pessimistic assumption that such influences must always be successful in their nefarious work is vitiated by his own example of the persistence of a real and active legal detachment through many centuries of close contact with the turbulent forces of history.

It may be urged that the law, although employing the method of impartiality, is in its content merely the embodiment of the interests of the most powerful social group, and in that most important respect unfree; and it can be argued that a socially directed science, although free to be critical and objective, would have its attention fixed down to problems chosen for it by social forces outside its own control. But speaking as an embryologist of no cash value to anybody, addressing a physical chemist of enormous industrial importance, I should like to ask Prof. Polanyi if something of the sort is not true already. Our civilization is, to some degree, a society and not a mere collection of individuals. Men of science are, again to some degree only, involved in the social bonds which create the coherence of society. One could only be justified in calling for a less degree of involvement in those bonds if one disapproved of the society as a whole; if, for example, one was a revolutionary who wished to stay outside it so as to overthrow it.

Science and Government

THE recent communication by R. H. F. Finlay[1] represents a point of view which seems to have some currency at the present time: the right of 'science' to govern. Is not this a threat to freedom? Since the foundation of science is the confession of truth, should we not admit that divided counsels are the breath of science; that not 'certainties' but hypotheses and theories form the stuff of science; that the conclusions of science are no more than provisional opinions based on evidence; that men of science have the virtues and vices of the politicians, trades unionists, lawyers, business men, peers and prelates through whom we govern ourselves to-day; that the omniscience proper to the law and so to government is foreign to science; and that the part of science in the government (a part for which there is unbounded scope) is the provision of knowledge? For if 'science' assume authority, and the current beliefs of science have the force of law, freedom of opinion must perish and truth be shackled indeed.

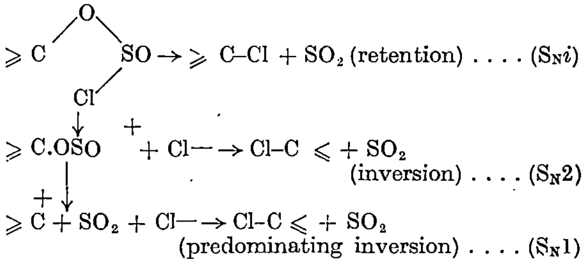
The Walden Inversion in the Replacement of Hydroxyl by Halogen

THE first serious study of the steric course of this replacement was that of Frankland[1], who concluded that phosphorus pentachloride always substitutes with inversion of configuration, whilst thionyl chloride does so except when a phenyl group is attached to the seat of substitution. Although this inference represented a remarkable advance, it is not quite correct, and also requires to be generalized. We have established that all the common substituting agents (PCl_5, $SOCl_2$, HCl, PBr_5, etc.) produce inversion unless a sufficiently powerful assembly, critical for each reagent, of electron-releasing groups at the seat of substitution reverses this result. For example, such an assembly, effective for all the reagents named, is present in the alcohols $CHPhBu^{a}.OH$ and $CHPhBu^{iso}.OH$. (We have carried out an improved resolution of the former and a new resolution of the latter.)

Kenyon, Lipscomb and Phillips first noticed[2] that in structures in which thionyl chloride ordinarily substitutes with retention of stereochemical form, it will substitute with inversion in the presence of sufficient pyridine. This is likewise a special form of a more general result, and we have in fact generalized it to include other substituting agents. For example, it applies to the action of phosphorus pentachloride on the two alcohols mentioned above.

Kenyon and Phillips attributed their phenomenon to the liberation of chloride ions[3], and, leaving aside details which Balfe and Kenyon have since explicitly modified[4], there is no doubt that they were right in their conclusion. However, because Gerrard[5] has cast doubt on their interpretation by emphasizing complications which we should not expect it to cover, we desire to direct attention to a recent general discussion of the problem, and to new observations on an aspect of it which is apparently in opposition, and is actually, in a certain sense, complementary to that illustrated in the phenomenon of Kenyon and Phillips.

In our discussion[6] we assumed that the first step in these substitutions is the formation of a condensation product or 'complex' such as $\geqslant$ C.O.SO.Cl, which can either eliminate the halide ion afterwards responsible for bimolecular or unimolecular substitution (S_N2 or S_N1), or, given a sufficiently facile electron-release from carbon to oxygen, can eliminate an oxide, thereby effecting an internal substitution (S_Ni); known principles determine how the stereochemical result depends on the mechanism followed:



(retention) . . . . (SNi)
(inversion) . . . . (SN2)
(predominating inversion) . . . . (SN1)

The effect of pyridine is explained as a competition of the type S_Ni *versus* S_N2; although the entity substituted in the S_N2-process, which the pyridine promotes, might be $\text{R.OSO}\overset{+}{\text{P}}\text{y}$ or R.OSOCl rather than R.OSO +, and analogously for other complexes. Thus halide ions produced by decomposition with a base promote substitution with an inversion of configuration.

But now, in the absence of a base, and in the presence of a good solvent for carbonium ions, we ought to be able to set up the alternative competition S_Ni *versus* S_N1. Let us consider the effect of chloride ions in this case.

With this object we refer to a recent demonstration[7] that reactions dependent on a preliminary rate-controlling ionization can with certainty be diagnosed when it is possible to observe that the anion produced, by participating in a reversal of the ionization, depresses the rate of the measured reaction. Applying this principle to the present problem, we see that, provided the ionization of the complex is rate-controlling, chloride ions, by reversing this ionization, can favour reaction S_Ni, and thus promote substitution with a retention of configuration.

Using several alcohols of the correct structural type and various substituting agents, we have set up the contemplated conditions by operating in liquid sulphur dioxide, chloride ions being supplied in the form of either triphenylmethyl chloride (a strong electrolyte) or tetraethylammonium chloride: the predicted effect has been observed repeatedly. For example, the alcohol $CHPhBu^{a}.OH$ and phosphorus pentachloride in sulphur dioxide gave $CHPhBu^{a}Cl$ with a rotation $+ 16{\cdot}5°$, whilst a comparative experiment in the presence of only 0·012 *M*-triphenylmethyl chloride yielded $CHPhBu^{a}Cl$ of rotation $+ 87{\cdot}7°$; the positive sign of $\alpha^{20°}_{D}$ ($l = 1$) corresponds to a retention of configuration.

Comparing this effect with that produced by bases, one understands that chloride ions may quite reasonably do opposite things in different circumstances, and this emphasizes the danger of discussing such phenomena from too limited a viewpoint. Our full results will be published later.

Viscosities of Three Classes of Liquids

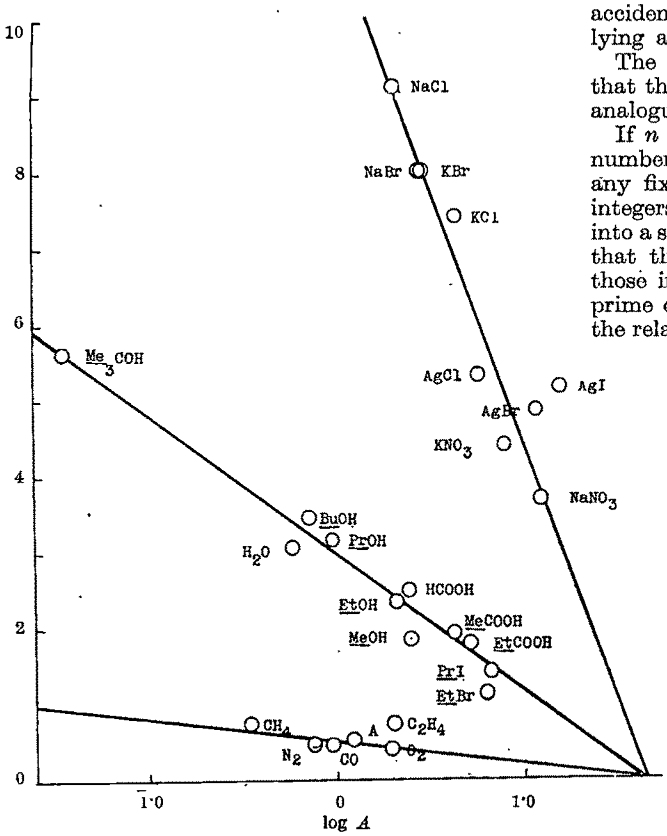
The variation of the viscosity of a great number of liquids can be expressed by Guzmán's equation[1]

$$\eta = A\, e^{B/RT}. \qquad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The values of the constants *A* and *B* for many liquids have been given by Ward[2]. It is now found that an approximately linear relationship holds between the values of *B* and log *A* (Fig. 1). Ionic liquids, hydroxylic liquids, and non-polar liquids have representative points close to three separate straight lines which appear to have a common origin (1·65, 0) on the log *A* *versus* *B* graph. Hence

$$B \cong m(1{\cdot}65 - \log A), \qquad . \quad . \quad . \quad . \quad (2)$$

where *m* is a different constant for each of the three classes of liquid. The graph points for the four alphyl halides cited by Ward (*loc. cit.*) lie just below the line



for the hydroxylic liquids ; two of these points are shown in the graph. The data given by Ward for metallic liquids do not follow equation (2).

Since B is an energy term which corresponds roughly to the latent heat of fusion, equation (2) recalls the energy and entropy relationships found for other properties of liquids[3].

Statistics and Prime Numbers

EINSTEIN's statistical theory of Brownian motion has two aspects, one dealing with distribution in time, the other with distribution in space. It is known[1] that, while the spatial distribution is described, as in the chronology of a Geiger counter, by Poisson's enumerating law of independent rare events, the temporal distribution turns out to be determined by the classical theory of independent frequent errors. Precisely in view of the latter theory, and in view of the ergodic hypothesis, the spatial distribution requires a more specific model than does the temporal distribution ; the former dealing with accidental fluctuations, the latter only with the underlying average state.

The object of this note is to point out the fact that this ambivalence in distribution has a complete analogue in the theory of prime numbers.

If n is a positive integer, let $\nu = \nu(n)$ denote the number of its distinct prime divisors, where m is any fixed positive integer or zero. If all positive integers which exceed unity are thought of as parcelled into a sequence of 'urns' $U_0, U_1, \ldots$ in such a way that the urn U_m contains the infinite sequence of those integers which possess exactly $m + 1$ distinct prime divisors, then the ratio $\pi_m(n) : (n-1)$ supplies the relative frequency ('probability') of those integers which are in the m-th urn and do not exceed n ; while $\nu(n)$ represents only a single cross-section of this infinite sequence of information.

The result corresponding to the normal distribution law in the theory of Brownian motion is represented by the following limit statement, which goes back to Hardy and Ramanujan and was recently proved in its sharper form by Erdös and Kac[2] : *If the deviation is measured on the scale of* $(\lg \lg n)^{1/2}$, *the distribution of the deviation of* $\lg \lg n$ *from the arithmetical mean of the values attained by the function* ν *of* n *on the range up to* n *tends to the symmetrical normal distribution of unit standard deviation, as* n *increases indefinitely.*

In view of the apparent parallelism between the average Brownian state and its accidental fluctuations on one hand and the single function $\nu(n)$ and the sequence of functions $\pi_0(n), \pi_1(n), \pi_2(n), \ldots$ on the other hand, the answer to the delicate problem concerning the distribution over the various urns $U_0, U_1, U_2, \ldots$ instead of the average distribution of their 'cross-section', will be expected to run as follows : *The positive integers not exceeding* n *are distributed over the various urns* $U_0, U_1, U_2, \ldots$ *in such a way that, in accordance with the law of independent rare events, the distribution is asymptotically represented by the Poissonian law of standard deviation* $(\lg \lg n)^{1/2}$, *if* n *increases indefinitely.* It will now be shown that this statement is correct, and that it is, as a matter of fact, a mere restatement of the prime number theorem.

A distribution over a sequence of discrete 'events' is called Poissonian if there exists a positive number λ such that the probability of the realization of the m-th event is proportional to $\lambda^m/m\,!$, where m varies through all positive integers and zero. Clearly, the factor of proportionality is $e^{-\lambda}$. The standard deviation is known to be $\lambda^{1/2}$. If the m-th event is represented by the presence of a positive integer in the m-th urn, U_m, where the positive integer is chosen at random among all positive integers not exceeding unity, then the relative frequency of the m-th event is $\pi_m(n) : (n-1)$, provided that the positive integer is restricted to be not greater than n.

Accordingly, the statement is that this relative frequency becomes asymptotically proportional to the Poissonian probability $e^{-\lambda}\lambda^m/m!$, where the standard deviation, $\lambda^{1/2}$, is stated to be $(\lg \lg n)^{1/2}$, while m is arbitrarily fixed. In other words, what has to be verified is that if m is arbitrarily fixed, $\pi_m(n)$ is asymptotically proportional to $n(\lg n)^{-m}/n\,!$. But it is shown by a well-known elementary calculation, which was apparently first carried out by Gauss[3], that if this asymptotic proportion is true for the particular index $m = 0$, then it is true for every fixed m. Since the asymptotic proportion reduces for $m = 0$ to the prime number theorem[4], the proof is complete.

Rust-Resistant Wheats for Egypt

OUR results resemble those obtained by Mehta and Pal[1] in India so closely that we are prompted to report them here.

All three rusts of wheat occur in Egypt, but the greatest loss in yield is caused by black rust on *vulgare* wheats in the Delta; our data indicate that the average annual loss is not less than 10 per cent of the possible yield, or about 2½ million bushels. The barberry plays no part here in the annual recurrence of black rust, for it is not found in or near Egypt, and wheat plants are so rarely found in summer that it is unlikely that they carry over the rust. Air-borne spores of black rust have, however, been found coming from the north-west[2] and it may be that this is the main source of infection.

Indian *vulgares* are better suited to Egyptian conditions than any other imported wheats (with the exception of one Italian variety Mentana), and Egyptian *vulgares*, known as Hindi wheats, are of Indian origin. Hindi and Indian wheats have all been found to be highly susceptible to black rust in Egypt, and interspecific crossing was thus resorted to in an attempt to obtain a resistant *vulgare*. We have produced a moderately resistant *vulgare* variety Mabrook from Giza 7 (*vulgare*) × Beladi 42 (*pyramidale*) which gives about 17 per cent higher yield than Hindis in the Delta, mainly because of its increased seed size and weight.

A large number of imported varieties have been tested for their resistance to black rust in Egypt, and as was the case in India we have found some *vulgares* with a promising degree of resistance in a group of Kenya wheats kindly supplied by the Director of Agriculture, Kenya, and by the Director of Plant Breeding, Department of Agriculture, New South Wales, Australia. Under Egyptian conditions these varieties are poor yielders and, according to our requirements, have other undesirable characters.

Since 1936 we have been crossing them with Egyptian wheats and we have obtained some F_4 and F_5 lines which are very resistant, give high yields and possess other desirable characters. *UX9M1A3* (Kenya) crossed with Giza 7 has given lines which are more resistant than the parents and in fact are almost completely resistant. Giza 7, from Federation × Indian 7, is less susceptible than Hindis and is our best quality Egyptian wheat. The Kenya parent shows quite a high degree of resistance, and we are informed that it is of unknown hybrid origin. We find that it has a gene for waxless foliage which is the dominant allelomorph of a gene for waxy, whereas waxy is usually dominant to waxless in *vulgare*. This indicates that it may have arisen from an interspecific cross, obtaining the dominant waxless and its rust resistance from the tetraploid parent.

The physiological races of black rust in Egypt have not been determined, but the above evidence suggests that they may be the same as those found in India.

The discovery of resistant *vulgares* has simplified our problem, and it appears that already we have made good progress towards the production of a resistant variety which is suited to Egyptian conditions and requirements.

Riboflavin in Black Pepper

Fixen and Roscoe[1] quoting Murthy[2] place the fresh green berries of *Piper nigrum* extraordinarily high in the list of riboflavin-containing materials. Commercial black pepper, which consists of the dried berries of this plant also picked in the green stage, was considered as a possible source of riboflavin. When this product was assayed for riboflavin by the method of one of us[3] it was found to be devoid of riboflavin. An aqueous extract gave a very strong green fluorescence at high dilutions, but the solubility properties of the fluorescent material were not those of riboflavin but were similar to those of piperine. That this is the substance in black pepper which is responsible for the observed green fluorescence is confirmed by the strong fluorescence obtained with purchased piperine at a dilution in water of 1 in 2 million. Piperine in alcohol solution gives a light blue fluorescence with ultra-violet light, and in chloroform a purple blue fluorescence is seen. The fluorescent material in black pepper behaves in a similar manner to piperine, whilst riboflavin gives a green fluorescence in both water and alcohol, and luminoflavin fluoresces green in alcohol, chloroform or water solutions.

Murthy uses an isolation method based on adsorption on fullers' earth, and admits the desirability of confirming the high value which he obtained for pepper by animal tests. We are of the opinion that when dealing with material of unknown fluorescent behaviour it is advisable to define riboflavin as a substance with a green fluorescence which is insoluble in chloroform and which after exposure to ultra-violet light in $N/2$ sodium hydroxide becomes chloroform-soluble without loss of fluorescence.

RESEARCH ITEMS

Upward Movement of Soil Solutes in Plants

THERE is now satisfactory evidence that solutes can move up the wood alone in amounts approximating those moving in intact stems, but the evidence concerning movement in bark is scarcely so satisfactory. A re-examination of this latter point has recently been made by Mason and Phillis (*Ann. Bot.*, N.S. 4, 765; 1940). Sea Island cotton plants are approach grafted and the weaker top removed, leaving a plant with one top and two root systems, one the 'main' root and one the 'side' root. The plants are grown under conditions of nitrogen starvation up to the time of the experiment, when the main root is immersed in solutions richer in nitrogen and the side root in a calcium sulphate solution. In one set of plants a half-inch ring of phloem is removed between the fork and the side root, and a half-inch segment of wood from between the fork and the main root. In a second set ('normal') the stem between the fork and the side root is severed. Both sets therefore receive adequate water, and nitrogen is absorbed only by the main root. All plants are harvested after five days and analysed for nitrogen and for bromine, which was also added to the culture solution bathing the main roots. Both sets are compared with an initial collection. Increase in both nitrogen and bromine is found to be significant in the plant as a whole and in the tops, for both 'normal' plants and 'cut wood' plants. Uptake was, however, considerably diminished in the latter group. Only traces of bromide entered these plants, so that this ion must travel with difficulty in phloem. With nitrogen, although translocation to the top was considerably diminished in amount by the wood 'ring', about the same *proportion* of the nitrogen absorbed by the plant reached the tops as in normal plants. Nitrogen therefore passes up the bark alone at a rate approximating that in bark plus wood. Previous work has shown the same statement to be true also for wood alone. It is impossible to say which channel is most used by normal intact plants.

Structure of the Apple Cortex

W. H. SMITH (*J. Pom. and Hort. Sci.*, 18, 249; 1940) has investigated the relations between the size of a mature apple, size and number of cells in the fleshy tissues, its level of respiratory activity and its keeping quality. It is concluded that the histological structure of the cortex of different varieties is related to their physiological behaviour. Apples with a longer growing season were found to have a smaller number of constituent cells in unit weight of tissue and a greater degree of cell enlargement, associated with relatively low respiration rate and good keeping quality. In short-season varieties there was a larger number of smaller cells, high respiratory activity and more rapid rate of senescence. The amount of cell multiplication varied with variety and largely determined typical fruit size. Within a variety, average cell size was correlated with the weight of the mature fruit, larger apples having larger cells. The number of cells was also greater in larger apples than in smaller ones of the same variety. Fruit size at maturity was thus determined both by amount of cell multiplication and degree of cell enlargement.

Nodule Bacteria and their Hosts

THE relative efficiency of nodule bacteria which attack leguminous plants has a very marked effect upon crop yield. Several factors appear to affect this efficiency, and H. K. Chen, Hugh Nicol and H. G. Thornton have recently investigated the part played by root juices of the host plant (*Proc. Roy. Soc.*, B, **129**, 475; 1940). Cultures of the nodule bacteria from soy bean and pea were treated with such juices obtained from plants with effective and with ineffective nodules. Extracts from roots with effective nodules produced a significant improvement in growth of the bacteria in a substantial number of the experiments. Juice from roots with ineffective nodules depressed the growth-rate of the bacterial cultures in several experiments, but the rate of increase of the different bacterial strains with root juice from uninoculated, nodule-free plants was not correlated with their effectiveness. It is evident that relations between the bacteria and their host are not always harmonious, and it is suggested that, as a result of infection, the plant produces soluble substances in its roots which, through their effect upon bacterial growth, can determine the relative efficiency of nitrogen fixation.

Pests of Garden Vegetables

G. FOX WILSON contributes a timely paper upon "Some Seasonal Pests of Garden Vegetables" to the *Journal of the Royal Horticultural Society* (**65**, Pt. 12; Dec. 1940). This reflects the author's flair for grouping pests according to their effects or their control, and is mainly written for growers of food. The economic entomologist will, however, find a little new documenting of his subject, such as a map showing relative distribution frequency of the cabbage white fly, *Aleurodes brassicæ*, in England and Wales, a photograph of a shaker blower for the application of nicotine dust, and a description of 'bloated' onions infected with the bulb eelworm, *Anguillulina dipsaci*.

Mutation Effects of Ultra-Violet Light

K. Mackenzie and H. J. Muller (*Proc. Roy. Soc.*, B, 1929, **691**; 1940) provide important data on the effects of ultra-violet light on *Drosophila melanogaster*. It is shown that the most effective wave-lengths for the production of gene mutants lie between 320 and 300 *m*γ, which correspond to those absorbed by nucleic acid. The incidence rate of gene mutants and structural alterations was studied in the same individual, and the authors' earlier results were confirmed that ultra-violet light, unlike X-rays, are ineffective in causing gross rearrangements in structure. Preliminary evidence indicates that minute alterations in structure are also rarely produced by ultra-violet light. This fact leads to important conclusions such as: (1) minute deletions and gene mutations are probably distinct; (2) activation of nucleic acid by radiation can give rise to gene mutation, but is ineffective in producing structural rearrangements; (3) the size of the gene may not be measured by ionization quanta since gene mutations occur secondarily as the result of a transfer of energy from nucleic acid as the primary effect. The atoms of the gene itself are not ionized specifically and directly by the ultra-violet light. The authors suggest that the relationship, if any, between cancer and gene mutations and ultra-violet light might be investigated with advantage in the light of this knowledge.

The Cheviot Granite

THE results of a recent detailed study of the Cheviot granite by A. G. Jhingran were communicated to the Geological Society at the meeting of January 22. The granite occupies an area of 22 square miles, but owing to a thick covering of peat and drift exposures are poor. Three main types are recognized: (*a*) the marginal variety, fine-grained and dark, with abundant plagioclase; (*b*) the Standrop variety, forming the central part of the area, relatively coarse-grained and light, with dominant orthoclase and abundant quartz; (*c*) the granophyric variety, containing biotite, occupying the ground between the others. Types (*a*) and (*b*) are pyroxene (diopside and hypersthene) granites. They contain numerous fine-grained inclusions which are composed of the granitic minerals, but with larger proportions of biotite and pyroxene. Chemically, a typical example falls at the silica-poor end of the variation diagram of the granitic types. The lavas around and included within the granite have been metamorphosed; but they seem to have caused little modification of the granite, if any. The variability of the granite is nevertheless probably due to contamination, but by Silurian greywacke and shale. A process of simple differentiation seems to be inapplicable, and no field evidence suggesting emplacement by successive injections has been found.

Mica in Tanganyika

THE pegmatitic mica deposits of the Uluguru Mountains, first discovered by Stuhlman in 1894, were successfully worked by the Germans until hostilities began in 1914. Under the direction of a British Military Board the industry was restarted in 1917. In subsequent years much prospecting was carried out and other important sources of mica—mainly of muscovite—were discovered. In 1920 the Government disposed of the various claims and private individuals began to operate, peak production being reached in 1925. Since then the industry slowly dwindled until 1937, when a revival set in. There are ample resources to meet a wide range of demands, and in order to stimulate further developments a report on the subject has recently been issued which makes available full information as to the geology of the mica fields and the conditions and requirements concerning prospecting, mining, grading and preparation, and marketing (G. J. Williams and A. F. Skerl, Tanganyika Terr. Dept. Lands and Mines, *Geol. Div. Bull.*, Dar es Salaam, 14, 47; 1940). The mica-pegmatites are restricted to rocks of the Lower Basement Complex, through which they are distributed fairly uniformly. It is noted that there is no spatial relationship between the pegmatites and either the older granites or the later central granite batholith of the Territory. This constitutes a serious objection to the traditional view that such pegmatites represent the residual fractions of granitic magmas. The authors favour the rheomorphic hypothesis and suggest that the pegmatites have been formed from palingenetic fluids, generated in depth, which may have migrated through a considerable vertical distance before deposition took place. Particulars are also given of lepidolite, in greisen-like pegmatite; phlogopite, associated with crystalline limestone or pyroxenite; fuchsite, a constituent of schists and quartzite; and vermiculite, associated with pegmatites cutting ultra-basic rocks.

Stability of Emulsions

EARLIER workers on emulsions regarded the interfacial electrical potential as an important factor in relation to the stability, but later work with protected emulsions indicated that the protective film of emulsifying agent conferred stability of the droplet in the emulsion; other recent workers believe that electrical conditions play a dominant part, but in some cases the emulsifying agents were liable to react with many of the electrolytes employed. A. King and G. W. Wrzeszinski (*J. Chem. Soc.*, 1513; 1940) have studied the influence of electrolytes on stabilized oil-in-water emulsions. No relation was observed between the electrical charge and emulsion stability in cases where chemical reactions were absent. The stability is ascribed to the properties of the film of emulsifying agent which surrounds each particle, which is generally strongly hydrophilic and, owing to hydration, is stable even at the isoelectric point. In the action of salts the effect of the anion is preponderant and is determined by its position in the lyotropic series. The destabilizing effect of any given salt on a particular emulsion is apparently due to the disruption of the absorbed film of stabilizing agent. There is nothing to differentiate between the stability of the film and of the emulsion. The concentration of the internal phase in the emulsion is also important in determining the stability in presence of electrolytes.

Internal Temperature of White Dwarf Stars

IN an important paper (*Astrophys. J.*, 92, 321; 1940), R. E. Marshak investigates in detail the probable condition of matter in the cores of the white dwarfs Sirius *B* and 40 Eridani *B*, with the view of deciding how the radiation from such stars is maintained and how they are likely to evolve in the future. Energy transport is found to be chiefly by radiation in the non-degenerate envelope; but by electronic conduction in the degenerate core. The free-electron density and the pressure are calculated for the radiative envelope, for the core, and for the intervening transition region; and then the equations of stellar equilibrium are numerically integrated through the surface regions and on into the interior. For Sirius *B* the thickness of the non-degenerate envelope and the internal temperature are calculated for various assumptions regarding the chemical constitution of the star: the envelope is found to extend over only 6 per cent of the radius at most, while the central temperature is found to be about 15×10^6 degrees C. for a Russell mixture of elements. At this temperature reactions between protons and other nuclei would go on very rapidly, and since the luminosity is so low, a negligibly small upper limit is deduced for the concentration of hydrogen in the core. This is true whether the source of energy is the carbon cycle or the proton-proton reaction. It is therefore concluded that the transmutation of hydrogen cannot account for the observed production of energy; thermonuclear processes are abandoned as the main source of energy, and recourse is had to the old gravitational-contraction theory, which gives a lifetime of at least 10^8 years before the white dwarfs cease to radiate visibly.

TELECOMMUNICATIONS TECHNIQUE AND BROADCASTING RECEIVERS

TWO papers which would, in normal circumstances, have been presented at the December and January meetings of the Wireless Section of the Institution of Electrical Engineers are now available. The full papers will be published in the June issue of the *Proceedings* of the Wireless Section, while extended abstracts are contained in the January issue of Part I of the *Journal of the Institution*.

The first of these papers is entitled "The Application and Use of Quartz Crystals in Telecommunications" and its author is Mr. C. F. Booth, of the Radio Branch of the Post Office Engineering Department. The piezo-electric crystal has played a major part in the advances which have been realized in telecommunications during the past ten years, and without its aid many radio-frequency generation and selection problems could not have been solved. Of the several crystalline substances possessing the piezo-electric property, quartz, tourmaline and Rochelle salt have been used in various phases of communications technique. The British Post Office has been actively concerned for many years with both the application and production of the quartz oscillator and resonator, and Mr. Booth's paper presents an account of this work and directs attention to some of its more important applications.

For the production of electrical oscillations of very stable frequency, whether for laboratory purposes or for the control of radio transmitters, the quartz crystal oscillator provides the simplest solution when a specific frequency in the range 50–200,000 kc./s. of stability better than $\pm 100/10^6$ is required, and it is almost the only solution for stabilities better than $\pm 10/10^6$. The type of quartz oscillator now in use has a frequency-temperature coefficient of less than $\pm 2/10^6$ per degree centrigrade, and while the output power obtainable from such an oscillator is small, this may readily be amplified up to the highest powers required for radio transmitting purposes. Much of the success of the widespread use of radio communication rests upon the ability so provided of maintaining radio transmitters upon their allocated frequencies within narrow tolerances. For example, a feature of present-day broadcasting involves the operation of several transmitters on the same frequency. Such transmitters may not vary in frequency by more than 1 c./s., and such stability has only been obtained in practice by means of a quartz oscillator control. In addition to such applications, the quartz crystal element may be associated with suitable electrical circuits to provide radio-frequency filters of a very high selectivity.

The chief source of good natural quartz is Brazil, and the selection and testing of such raw material and the production therefrom of suitably cut crystals for radio purposes is a highly specialized art. The paper referred to above includes a well-illustrated section describing in some detail the methods employed in the crystal laboratory of the Post Office for the production, adjustment and testing of quartz oscillators and resonators for use by that department in its many and widespread activities in the field of telecommunications. It is visualized by the author that the quartz crystal will play an increasingly important part in the ever-growing technique of communications.

The second paper is entitled "Broadcast Receivers: a Review"; and its authors, Messrs. N. M. Rust, O. E. Keall, J. F. Ramsay, and K. R. Sturley, are members of the staff of Marconi's Wireless Telegraph Co., Ltd. This paper comprises a review of broadcast receiver circuits and developments over the ten-year period from 1929 up to the outbreak of war. The first part of the paper has been compiled from an examination of more than a thousand circuit diagrams, and is a review of such receiver circuits which have stood the test of production. The broadcasting receiver is analysed stage by stage in the paper with the aid of typical diagrams, in an attempt to extract the salient technical features. It would appear, however, that as the sales market over the period under consideration consisted mainly of purchasers of first receivers, the trend of design was influenced by selling points rather than basic principles and potential users' needs.

Recognizing the limitations referred to above, the second portion of this paper is concerned with some fundamental problems and the lines of possible future development. Selectivity, fidelity, electrical interference and automatic accessory circuits for volume, frequency, selectivity and remote control are some aspects of receiver design to which attention is devoted. Up to date, two specifications, which attempt to define and assess the performance of broadcasting receivers, have been produced; one was first published in 1930 by the Institute of Radio Engineers in the United States, and has since been modified and extended; the second was published in Great Britain in 1936 by the Radio Manufacturers' Association. Such specifications were, however, found to be inadequate, and when happier times return they will have to be drastically revised to meet the needs of the broadcasting receiver industry.

The concluding portion of this paper refers to the difficulties accompanying the allocation of wavelengths to broadcasting stations, and the prevailing congestion in the long and medium wave bands. With the view of meeting these difficulties, there has been a tendency to urge the advantages of broadcasting over telephone lines and electricity supply networks. The authors point out, however, that the position might be ameliorated to a considerable extent if the channel width utilized was related to the programme requirements. Thus, instead of using uniform channels of 9 kc./s. nominal width, it would be preferable to allot a single side-band channel of 5 kc./s. for speech, and a 20 kc./s. double side-band for programmes requiring high quality. In such cases, transmitter and receiver design would need to be correlated, and opportunities for exploring this possibility may occur in the future.

DEEP-FOCUS EARTHQUAKES OF THE SOUTH-WEST PACIFIC

R. C. HAYES, of the Dominion Observatory, Wellington, New Zealand, read a paper on deep-focus earthquakes of the south-west Pacific at the Sixth Pacific Science Congress in 1939.* The Dominion Observatory at Wellington has for many years carried out the determination of provisional epicentres in the region south of the equator, lying between long. 140° E. and long. 160° W. In the region investigated, it appears that about 11 per cent of all the earthquakes have abnormally deep foci, and that about 60 per cent of the deep ones occur between lat. 10° and lat. 30° S.

It is found that the deep-focus earthquakes occur in most parts of the general seismic belt extending south-eastward from near the coast of south-eastern Asia, through New Guinea, the Solomon Islands and the New Hebrides to the region of Fiji, Tonga and Samoa. The belt of both normal and deep earthquakes thence appears to turn southward toward New Zealand, although the deep earthquakes apparently become less frequent as the New Zealand region is approached. There is no evidence of a continuation of this belt across the South Pacific toward South America, but there is a short extension north-eastwards to Samoa.

The occurrence of deep-focus earthquakes near the Kermedec Islands and New Zealand has been confirmed. According to Hayes, the earthquakes of October 30 and November 1, 1938, with epicentres north-east of Taupo in the North Island, had focal depths of the order of 200 km. Present evidence indicates that the western Pacific deep-focus belt, after turning southward from the Fiji region toward New Zealand, probably terminates just east of New Zealand in about lat. 42° S., or at least is interrupted at this point for a distance of about 400 miles.

Wadati, Berlage and Davison have previously noticed that in Japan, Manila (East Indies) and South America respectively the depth distribution of deep-focus earthquakes appears to increase in the 'continental' direction. Hayes states that the data so far available do not show very clearly whether this type of distribution exists in the south-west Pacific except in the Fiji region, where depths are definitely greater on the 'continental' side of the earthquake belt than on the Pacific side.

An important feature which Hayes has observed in some deep-focus earthquakes in the south-western Pacific is the remarkably large amplitudes sometimes recorded at Wellington of the phases *ScS* and *sScS*. When these are both observed, they provide a comparatively accurate method of determining focal depth.

FESTIVALS OF THE MIN CHIA, YUNNAN

RELIGIOUS festivals of the Min Chia, a non-Chinese tribe of Yunnan, have been described by C. P. Fitzgerald (*Man*, December 1940) to illustrate that their acceptance of Chinese culture, in so far as religious belief and practice are concerned, is less complete than outward appearance would indicate. While the Min Chia in fact are acquainted with a form of Buddhism, they worship a number of non-Buddhist deities and practise the rites of ancestor worship ; but it is not correct to say that they have three religions. In practice the worship of the Buddhist Boddhisatvas and Taoist deities forms one religion served by the same rite—burning incense before the shrine—and attended by the same people, usually women and girls. It may be contrasted with ancestor-worship, in which women take a less active role, and which is a private family affair without public festivals or temples.

Of the ancestral ceremonies, one of the most elaborate is the Shu Bao or "burning the bundles", which takes place on the 15th day of the 7th lunar month (in 1937, August 19) for the purpose of dispersing the ancestral spirits after their annual sojourn of fourteen days in the home. It takes its name from the burning of bundles of 'books' of Chinese poems, on each of which is inscribed the name of an ancestor, to a total number of perhaps one hundred individuals, extending back to the tenth generation.

A festival characteristic of the worship of local deities is the Gwer Sa La, a dance festival held in the villages along the lake north of Ta Li on the 25th of the fourth lunar month (May) between the gathering of the wheat harvest and the transplanting of the rice seedlings. Young men dancers, arrayed in costumes in some ways suggesting those of women, pass through all the villages on the lake shore, dancing at each, singing and acting in a half-intoxicated manner, both they and the spectators behaving boisterously. The last dance is always in the Mer Ger Yu village, and after a feast the dancers disperse, before the last act of the festival in which the tablet of the ancestor of this village is carried in procession in a litter to a spot a mile distant at the edge of the village lands, where the arrival of the last body of dancers is awaited. All return, the dancers dancing continuously, to the village, and after a final dance the tablet is returned to the temple and a feast follows.

The meaning of the rite is obscure, though it is said to be intended to bring benefit to the rice crop. The dancing at this feast is identical with the performance of a class of exorcists known as *sai dser*, which may mean "westerners".

FORTHCOMING EVENTS

Tuesday, February 18

Institution of Civil Engineers (Joint Meeting with the British section of the Société des Ingenieurs civils de France) (at Great George Street, London, S.W.1), at 1.30 p.m.—M. Tony Jules Gueritte: "Further Data concerning Pre-Stressed Concrete: Comparison between Calculated Stresses Registered during Tests".

Wednesday, February 19

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. Julius Grant: "Art and Science in Paper Manufacture".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Dr. E. Greenly: "The Glacial Phenomena of Arron". Mr. B. C. King: "The Cnoc na Cuilean Area of the Ben Loyal Igneous Complex".

Friday, February 21

Institution of Mechanical Engineers (at Storey's Gate, London, S.W.1).—Annual General Meeting. Lt.-Col. P. H. Johnson: "The Mechanical Requirements of the Royal National Lifeboat Institution".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Two Assistant Lecturers in Mechanical Engineering at the Ipswich School of Engineering—The Secretary for Education, Tower House, Ipswich (February 21).

Lecturer in Mathematics and Science at the Chesterfield Technical College—The Clerk to the Governors, Technical College, Infirmary Road, Chesterfield (February 22).

Vice-Principal at the Arab Women's Training College, Palestine—The Secretary (I.P.R.), Board of Education, Alexandra House, Kingsway, London, W.C.2 (February 24).

Graduate Lecturer in Mathematics and Physics at the Burnley Municipal College—The Director of Education, Education Offices, Burnley (February 24).

Principal of the Shrewsbury Technical College—The Secretary for Education, Education Office, County Buildings, Shrewsbury (February 26).

Director of Education to the Isle of Wight County Council—The Clerk to the County Council, County Hall, Newport, Isle of Wight (February 26).

Lecturer-in-Charge, Department of Coal Mining, Technical Education Branch, Department of Public Instruction, and a Lecturer upon Coal-Mining Engineering, etc., University of Sydney—The Official Secretary, New South Wales Government Offices, 125 Strand, London, W.C.2 (February 28).

Principal of the Salisbury Diocesan Training College for Women Teachers—The Hon. Secretary, Diocesan Training College for Women Teachers, The Close, Salisbury (March 1).

Headmaster of the County School for Boys, Beckenham and Penge—Mr. G. Crease, 12 Beckenham Road, Beckenham, Kent (March 8).

Demonstrator in the Departments of Chemistry and Pharmacy—The Registrar, Portsmouth Municipal College, Portsmouth.

Assistant Engineer by the Government of Dominica (British West Indies)—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9551).

Engineer for the Public Works Department of the Government of Sierra Leone—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9552).

Engineering Assistants at the Air Ministry—London Supplementary Register Office, Ministry of Labour and National Service, 4 Great Marlborough Street, London, W.1 (quoting Order No. 472).

Lecturer in Mechanical Engineering and Two Lecturers in Electrical Subjects at the Rotherham College of Technology and Art—The Director of Education, Education Offices, Rotherham.

CO-ORDINATION OF THE NATION'S RESOURCES

RECENT debates in the House of Commons on man-power and production have indicated an increasing concern with the direction and co-ordination of our economic effort. The announcement that Lord Stamp has reported to the Prime Minister that the work of surveying economic and financial plans which he undertook with the assistance of Mr. H. G. Henderson and Prof. Henry Clay can now be brought to an end, suggests that a definite stage has been reached in this matter.

There are, of course, fields in which economic affairs, as in that of economic warfare, overlap with considerations of offensive warfare itself; with our comparatively limited resources of man-power its apportionment between war production, essential services, civil defence and those of the highly mechanized armed forces is no simple matter. Without, however, a clearly defined policy and accurate knowledge, waste and overlapping are almost inevitable.

Of the danger of departmentalism the Ministry of Aircraft Production provides a sufficient illustration. Despite the wonders Lord Beaverbrook worked last summer in accelerating the production of fighters, his methods have as conspicuous defects as merits. Refusal to co-operate or co-ordinate, and war with other departments as well as on the Nazis, are no service to our total effort when they upset the programme of other departments. Moreover, the administrative task is not simply that of balancing or co-ordinating rival demands. It involves the harmonizing of the policy as well as of the programmes pursued by such closely related departments as, for example, the Ministry of Food and the Ministry of Agriculture, or for another example, of the Ministry of Food and the Ministry of Health.

When departmental decisions or policy may affect not only the internal efficiency or purposes of that department but may even impair or frustrate the programme and policy of another independent department, some co-ordination and guidance from above is clearly demanded. Nor is this the whole difficulty. Our economic policy or strategy must have regard not merely to affairs in Great Britain but also to the economic position of the Dominions and Colonies, and of our allies and well-wishers in other countries. Nothing less than the maximum and most efficient use of the full economic resources of the whole Empire will suffice for our success in this struggle.

There have already been reminders of these interactions from time to time as restrictions have been placed upon imports of foodstuffs or other commodities. The recent decision of the Government to reduce or prohibit imports of fresh or canned fruit are a pertinent example that such matters do not end with our own self-denial. From the point of view of conserving shipping tonnage these may be wise precautions, but their reaction on the countries thus deprived of their markets, such as South Africa and Jamaica, may have a significant effect on the economic front of our total war effort.

Jamaica, for example, is one of the poorest of the British West Indian Colonies, and her poverty will be desperately increased now Great Britain is no longer to take her bananas, which normally account for half her total exports and were almost entirely imported by Great Britain and the now blockaded countries of Europe. A disastrous hurricane and the spread of disease had already badly affected the banana trade last year, and exports in the first half of the year were only a fraction of what they were a year earlier. While the trade has no more than meagre reserves, sugar-rationing has blighted Jamaica's only hope of expansion in an alternative crop, and a food production scheme launched a few months ago has been hampered by the absence of sufficiently attractive prices and by unemployment among the middle classes providing the market for such new output.

This situation can scarcely be ignored by the Secretary of State for the Colonies in view of the recommendations of the Royal Commission on the West Indies which the Government has already accepted, and the policy to which we have been committed by the inauguration of the new Colonial Development Fund. The restriction of these food imports therefore may well involve increasing the substantial British financial help to Jamaica as well as exploring the possibility of outlets for her produce in the Dominions and the United States. Other parts of the Colonial Empire which have been responding so splendidly to the call of the Motherland may also require financial or other help in similar ways as a repercussion of restrictions at present imposed by us on their markets.

The matter is, however, one which has a direct connexion with the plans which the Ministry of Economic Warfare is already formulating for the management of the great surpluses of food and raw materials now accumulating in different countries. These plans are concerned with the problems that will face us when the War is over: the task of meeting the immediate needs of Europe. Within the boundaries of the Empire it should at least be possible to consider them in relation to the financial and economic needs and resources of the Empire at war, and to minimize the dislocation and distress occasioned by the disruption of the individual economy of Colony, Dominion or Motherland under immediate exigencies. Wisely conceived with a view to such policies, the work of the Interdepartmental Committee, of which Sir Frederick Leith-Ross is chairman, appointed by the Minister of Economic Warfare, might well provide the Minister of Food or other colleagues with valuable data enabling them to achieve their own ends with less friction or dissipation of colonial and imperial resources.

This is indeed yet another field in which planning to meet post-War problems may assist in the solution of those of a war-time economy. The Interdepartmental Committee has clearly a double function. Its purpose is to mitigate present embarrassments of overseas producers deprived through the War, whether by the British blockade, food policy or in other ways, of many of their normal markets, as well as to prepare in advance for the relief at the earliest possible moment after their liberation of the plundered countries the resources of which are being ruthlessly drained to serve the Nazi war machine. It should not be forgotten that the appointment of this Committee brings a message of hope to the inarticulate victims of Nazi depredations. Effective publicity in these unhappy countries for the work on which the Leith-Ross Committee has embarked might be far more valuable to the British cause than a premature statement of war aims, and in itself provide a most effective answer to the challenge of the new order or regulation through Nazi domination in Europe which has been so blatantly proclaimed.

The problems which confront the Committee are indeed complex, and the statement on economic warfare broadcast a short time ago by Dr. Hugh Dalton to the United States was framed to invite the co-operation of the United States. While the most immediate problems are those of finance and storage, the eventual problems of shipping and distribution call for consideration in advance, in the light of the experience accumulated after the armistice of 1918. Exact conditions cannot be forecast, but some broad estimate of needs and the points where they are likely to be most acute should not be impossible.

Nor is this all. The problems of future production also intrude themselves. Beyond the immediate needs of Europe lies the larger task of constructing a scheme for co-operative planning which will put an end to the gross inequalities between people and people, man and man, that are the disease of our modern life and the cause of much of our economic confusion. If, indeed, we can solve this problem of surplus production, we may break down the system of high tariffs and other restrictions.

The issues with which the Committee is dealing have indeed more than passing significance. They impinge directly on the world-wide problem of bridging the gap between producer and consumer, of co-ordinating the different types of production suited to different regions and of planning distribution and exchange. As Dr. Dalton put it, we must finish with the economics of scarcity and anarchy; we must build the new economics of plenty founded on a rational plan. To extend the immense productive reserves of the world both to relieve poverty and to create a new standard of living, and in so doing to lift the spectre of unemployment from millions, is a constructive task in which we may well look for the comradeship of the American people.

None the less it is true that along such lines our own efforts should assist eastern Europe to build a life less exposed to the rival ambitions of great Powers and less distracted by the animosities of race. With the breakdown of high tariffs and other restrictions and the use of our common resources to develop the economic life of the poorer States by expenditure on roads and transport, education, co-operative institutions, and schemes of nutrition, eastern Europe should acquire a well-balanced economy in which primary production and industrial expansion are complementary. If we can put courage and imagination into our schemes for reconstruction, democracy, by rescuing eastern Europe, may at once attest its own vitality and superiority to the dictatorships and its claims on the help of the American peoples in these even wider constructive schemes inherent in a world economic plan. Whether indeed we face the immediate problems of our own war-time economy, calling for single-minded direction and co-ordination through a Minister of Economics, or their impingement on the immediate post-war problems confronting the Leith-Ross Committee, the need is for the vision, courage and creative statesmanship which are the secret of every major advance of man.

RECENT TRENDS IN PSYCHICAL RESEARCH

Experiments on the Paranormal Condition of Drawings. By Whately Carington. **Fresh Light on Card Guessing.** By S. G. Soal. *Proceedings of the Society for Psychical Research*, Part 162, June 1940.

The Ultra-Perceptive Faculty
An Experimental Investigation. By Dr. J. Hettinger. Pp. 204. (London: Rider and Co., n.d.) 12*s*. 6*d*. net.

IN the course of the last few years, a change has become apparent in the attitude of serious students in psychical research, not only as regards the nature of the problems with which they are called upon to deal, but also as to the methods by which those problems should be tackled. As progress is made along the whole scientific front, so new methods, devised for specific problems, can often be turned to account in dealing with points the elucidation of which was not envisaged when the novel means of attack were first planned.

The problems of psychical research, as is now sufficiently well known, can be roughly but conveniently divided into two main groups, which are generally called the physical phenomena and the mental phenomena. The former class comprises such occurrences as telekinesis, materializations, apports and such-like; whilst the latter consists of the subjective or psychological manifestations concerned with the various automatisms, trance mediumship and the host of varied occurrences which have often been associated with a supposed telepathic or clairvoyant faculty.

As regards the physical phenomena, it can be said with some degree of truth that very little progress has been made during the last fifty years. Indeed, during recent times frauds and mystifications have become so frequent, and the incompetence and disingenuousness of certain investigators so marked, that many students have turned away in disgust and concentrated all their attention upon the psychological side, where better control conditions can often be secured.

Apart also from the dubious nature of the physical phenomena themselves, the difficulties of obtaining repeatable experiments have proved almost insuperable; and thus accounts of these manifestations have remained on the anecdotal plane, to be appraised for what they are worth, but often of little real interest except for those who view them from the historical or anthropological aspects.

The Society for Psychical Research has always been keenly aware of these weaknesses and difficulties, and so far back as 1883 Prof. F. Y. Edgeworth contributed a paper to the Society's *Proceedings* in which he dealt with the calculus of probabilities applied to this subject. Again, in assessing the value of the successes in the card-guessing experiments conducted by the late Mrs. A. W. Verrall about 1890–95, the formulæ for calculating probability were used by Mr. C. P. Sanger; and for some years afterwards it was always felt that some method for estimating chance factors was urgently needed when dealing with questions in which telepathic and clairvoyant factors seem to have been indicated. It was not, however, until 1928 that Miss I. Jephson published a paper in the Society's *Proceedings* in which she described the results of a series of card-guessing experiments. Although perhaps her data were not sufficiently controlled, her methods of dealing with them had much to recommend them. Statistical theory and technique had progressed since 1890, and Miss Jephson availed herself of the methods of scoring coincidences in tests with playing cards which had been devised by Prof. R. A. Fisher about 1924, and afterwards modified by him in view of the problem presented by the card preferences exhibited by certain persons who offered themselves as subjects for experiment.

The scoring technique devised by Prof. Fisher not only furnished a score where a guess is correct but also a score for a partially correct guess. Thus if the actual card is the ten of clubs and the ten of spades is guessed, then there is a greater degree of success than if the percipient had guessed the queen of hearts. This development of the statistical method as applied to the problems of psychical research is now rapidly proceeding and bids fair to occupy the centre of the controversial stage for some years to come. The turmoil aroused in psychological circles in the United States concerning the question of what has been called 'extra-sensory perception', as formulated by Dr. J. B. Rhine and his colleagues at Duke University, is now becoming crystallized around fewer points, since the attacks on the statistical technique employed have almost entirely failed and the great improvement, both in the soundness of the data and their presentation, have led to a general tendency to view the whole question in a more favourable light.

It is the feeling that psychical research, in order to produce more fruitful and reliable results, must employ quantitative methods to a far greater extent than hitherto, which has inspired the work of Messrs. Carington, Soal and Hettinger, bibliographical details of which can be seen above. How far, it may be asked, are the 'coincidences' so frequently met with in this subject 'real' coincidences, and how often might they be said to happen 'by chance'? Can we obtain a probable chance-frequency by which the results can be judged? Do the figures, if they can be obtained at all, show significant results, or merely a result which, judged purely from the statistical point of view, can certainly be ascribed to what we call 'chance'? In other words, the problem is one where we have to ask ourselves whether the data provided by certain branches of psychical research are analogous, or can be made analogous in all important respects, to those other fields of research where the statistics of probability are generally accepted, such as in questions arising from the consideration of games of chance or experiments depending upon random sampling and suchlike.

In the case of the three authors now under review, the claim is made that experiments have been devised which exhibit significant results, and show clearly that something other than the chance factor is present. In all three cases the most rigorous conditions prevailed, and normal, simple sources of error such as leakage or fraud can, it seems, be safely dismissed. In Mr. Carington's experiments simple drawings were used for the test material. About 250 percipients took part and these were instructed to reproduce the drawings exhibited, normal knowledge of which being, of course, carefully excluded. Other sets of drawings were used as controls, and the scoring was carried out by an independent judge; the results being that the percipients tended to a highly significant extent to score relatively more hits on the original drawings of their own experiment than on the control drawings used in other experiments. A test control scoring of the same set of drawings against a randomized 'dummy' set gave a null result. Moreover, it appeared that the successes were not always of the 'now or never' type, where the hits occurred only on the occasion when the original drawings to which they seemed to refer were displayed. A certain displacement, both earlier and later, was to be noticed, and it was this which suggested to Mr. Soal that he should undertake a re-examination of some of the mass of data on card-guessing which he had collected and which had seemed to yield so little evidence of any non-sensory cognition.

From this examination emerged the discovery that two of Mr. Soal's percipients exhibited in their guesses the same kind of displacement effect remarked by Mr. Carington. Thus in one instance, of 2,000 guesses, the hits on the actual card intended to be transmitted were 447, giving a standard deviation of 17·89 and a value of χ (deviation/standard deviation) of $+ 2{\cdot}627$; the hits on the card before the actual card, 457 (standard deviation 17·53: $\chi = + 4{\cdot}164$); and on the card after the actual card, 442 (standard deviation 17·53: $\chi = + 3{\cdot}309$). In addition to this remarkable effect, of which the interpretation is still obscure, Mr. Soal has shown how the cards before and after the card to be guessed influence the results, thus suggesting that the card images are somehow known to the percipient before they emerge into consciousness.

The psychological implications of these results, which Mr. Soal has discussed in his paper, are obviously of considerable importance, and suggest that links between normal mental action and what is apparently going on during these obscure processes are already beginning to appear. However that may be, the discovery of this displacement effect may have considerable influence when the results of earlier experiments are assessed, since in these cases the investigators were concerned only with successes on the actual card or symbol exhibited, other guesses being generally neglected or reckoned as failures.

The methods pursued by Dr. Hettinger were somewhat different. In his monograph, which has been approved for the degree of Ph.D. by the University of London, he is at pains to show that modern statistical technique can be applied to statements made by mediums concerning objects submitted to them. In each test the items perceived by the medium relating to the subject with whose article he was dealing were presented to the subject for identification, mixed in some way with an equal number of control items, the subjects not knowing, of course, which was which. Six hundred and twenty-three tests yielded 6,631 items or statements; and of the total 13,262 actual and control items, 4,483 were accepted by the subjects as being applicable to them. Of these, 2,570 belonged to the subjects and 1,913 to the control or fictitious items, the result being calculated as 14·6 times the probable error.

Successful criticism of these results must, it seems, be based upon two main sources of suspected error. An attack can be made on the validity of the data upon which the computations are based; or, if this proves abortive, the statistical technique itself can be criticized. Since this technique is comparatively simple and based on well-recognized principles, an attack in this direction would seem to be somewhat hazardous, and recourse must be made to assailing the validity of the original data, evidence being offered to indicate unnoticed sources of error in their collection and treatment. Considering the extreme care and rigorous scrutiny by experts of every step that has been made in most of these experiments, such a criticism would doubtless be welcomed were it to be forthcoming. But it is in the repetition of the experiments by others and on a large scale that progress can best be achieved. Were such repetitions to exhibit the same puzzling features, then these new methods now being used in psychical research would prove to be fully justified, and we might reasonably expect that this exasperating study has at last turned the corner and is gradually passing from the anecdotal stage to that of a well-founded experimental science. E. J. DINGWALL.

POWER-TABLES

British Association for the Advancement of Science Mathematical Tables

Vol. 9: Tables of Powers giving Integral Powers of Integers. Initiated by J. W. L. Glaisher. Extended by W. S. Bickley, C. E. Gwyther, J. C. P. Miller, E. J. Ternouth, on behalf of the Committee for the Calculation of Mathematical Tables. Pp. xii+132. (Cambridge: At the University Press, 1940.) 15*s*. net.

THIS work is based on a table compiled by Glaisher about 1873, giving the first twelve powers of the first thousand integers. Only one copy of Glaisher's table is known to have survived, and it came into the possession of the British Association Tables Committee in 1935. It is not known how Glaisher computed his table, but it is so accurate that, apart from one missing digit, no error has been found in it.

Glaisher's work has now been largely extended. The present volume gives in full the powers of numbers 1 to 99 up to the 30th; the 31st to 39th and 41st to 49th powers of these numbers somewhat curtailed, the 40th powers in full, and the 50th powers of numbers 1 to 120 in full. For numbers above 100 the range of powers is not so great. The largest number dealt with is 1,099, of which the powers up to the 12th are tabulated.

A table of 50th powers is a majestic sight. The curve $y = 50 \log x$ stands out clearly on the page, shaded in by the digits of the entries in the table. Even 2^{50} has sixteen digits, while 120^{50} is a number of a hundred and four digits. Every fiftieth power is congruent to 0, 1, 249, 376, 624 or 625 to modulus 1,000, and these numbers are seen repeating themselves down the edge of the table. The entries do not go far enough to reveal any higher periodic properties.

For actual reading the tables soon get a little monotonous, and the introduction is to be preferred. This gives an interesting account of the methods of computation and checking, and suggests methods of interpolation which could be used. A bibliography gives a list of earlier tables, most of which have been checked by the present calculators, and lists of the errors so found.

E. C. TITCHMARSH.

A NEGLECTED THINKER

The Philosophy of Peirce
Selected Writings. Edited by Dr. Justus Buchler. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvi+386. (London: Kegan Paul and Co., Ltd., 1940.) 16*s*. 6*d*. net.

C. S. PEIRCE was a thinker of rare originality and depth, a logician brought up, as he said, in a laboratory. Nevertheless, though he influenced the development of mathematical logic in his lifetime, his general influence on contemporary thought has been almost entirely indirect, through friends, such as James, Royce and Dewey. His published writings, mostly short articles, have attracted little attention. The present reviewer has to confess that when he read a selection of these reprinted in 1923 under the title "Chance, Love and Logic" he failed to realize their value. Recently the great mass of manuscripts he left has been published, but few are likely to wade through the whole six volumes of his complete works. It is to be hoped, therefore, that this selection of published and unpublished work, with an excellent introduction by the editor, will make his work better known; for it is worth knowing in spite of its peculiar defects. Every now and again Peirce stated an important principle with force and clarity; but when he came to develop and explain it he tended to be pedantic and even confused and irrelevant. He had many of the faults as well as a good deal of the genius of Kant. He also suffered from being fifty years ahead of his time—he died in 1914 at the age of seventy-five. It must suffice here to mention three of his outstanding contributions to thought to be found in this book.

(1) It is often said that Peirce was the originator of Pragmatism; but his theory is not the same as James's. The starting point for Peirce was Alexander Bain's definition of belief as "that upon which a man is prepared to act". When this is applied to scientific belief it means that a theory prescribes certain operations to be performed and states the results that will follow the performance. If the results do not follow, the theory is false. If no kind of operation is prescribed by it, the theory cannot be shown to be false but is superfluous, and may be an obstacle to the formulation of the proper kind of theory. This attitude was novel in the nineteenth century though very generally accepted now. Peirce quite definitely avoided the fallacy of the Positivist or Phenomenalist view which leaves out the vital factor of "operations to be performed".

(2) Peirce was one of the first to realize that chance or randomness is a positive factor in the physical world, not merely a name for ignorance of causes, and that randomness on a microscopic scale is bound to lead to some kind of regularity on a macroscopic scale. Moreover, as he says, "those observations which are generally adduced in favour of mechanical causation simply prove that there is an element of regularity in Nature, and have no bearing whatever upon the question of whether such regularity is exact and universal or not. . . . Try to verify any law of Nature, and you will find that the more precise your observations, the more certain they will be to show irregular departures from the law. We are accustomed to ascribe these, and I do not say wrongly, to errors of observation; yet we cannot usually account for such errors in any antecedently probable way. Trace their causes back far enough and you will be forced to admit that they are always due to arbitrary determination, or chance" (p. 331). This was published in 1892. The general principle, of which Heisenberg's "Uncertainty Principle" is a special case, could scarcely be more definitely stated.

(3) The problem of the validity of inductive generalization has always been the logician's nightmare. Peirce goes to the root of the matter in a way that makes more recent writers on this subject look like mere fumblers. The first point he makes, generally accepted now but not in his own day, is that there is no complete certainty on matters of fact, only greater or less probability. Mathematical certainties are purely formal and would be the same if all facts were different. The second point which nobody else seems to have expressed properly is that the problem of inductive generalization is essentially one of sampling. The value of the information obtained from a sample as a guide to the character of the whole bulk of the material depends upon what we are looking for and how the sample is taken. If there is something in the bulk not revealed, however many samples are taken and by whatever method, then it is permanently latent and therefore negligible. If later samples reveal something that previous samples failed to reveal, the difference must lie in the method of sampling and is a genuine revelation of the character of the material. Where sampling takes the form of measurement, the calculus of errors provides a check on the value of the results, especially as to what improvement is to be expected by making further measurements by the same method. It shows that as a rule quite a small number of measurements properly made are very nearly as reliable as a very large number. Nothing like Mill's Principle of the Uniformity of Nature

is needed nor is it necessary to "postulate" anything. The only kind of *a priori* principle involved is like those put forward by Kant; namely, if anything is true universally of any aspect or part of experience it must be something involved in the conditions under which that experience is obtained. The questions to be asked are: What is known beforehand about the material to be sampled? By what method are the samples obtained and examined? From the answers to these questions we can assess the value of the generalizations in terms of probability. This explains why each inductive argument has to be considered individually on its merits and not in terms of general formal rules; why, though the notion of probability is involved, numerical values cannot be assigned; at the same time it makes clear that there is a common factor involved in all cases and the procedure is not merely irrational.

A. D. Ritchie.

TELEVISION ENGINEERING

Principles of Television Engineering
By Donald G. Fink. Pp. xii+541. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 33*s*.

PRIOR to the War, Great Britain had established a very advanced position in the application of radio communication to television broadcasting. The inauguration by the British Broadcasting Corporation of the London television station at Alexandra Palace in August 1936 marked the beginning of the first public television service in the world. Much scientific research and technical development in this subject were being actively pursued in several other European countries, and more particularly by various commercial organizations in the United States of America. Since the outbreak of war, the public development and application of television to broadcasting has been brought to a standstill in Great Britain, whereas the technique of the subject has continued to be very actively pursued in America during the past eighteen months. There is good reason to believe, however, that when happier times return, Great Britain will be able to recover a place in the front line of television broadcasting. A good deal of the technical work now being carried out for war purposes by radio engineers and physicists will probably find ready application to television problems when peace comes; while the recent demonstration given by Mr. J. L. Baird of television in natural colours indicates that the small amount of experimental work still in progress is already producing fruitful results.

In preparation for the expansion of the radio industry in America from normal sound broadcasting to include the very wide field of television, Mr. D. G. Fink's book, entitled "Principles of Television Engineering", is probably very opportune. The author is the managing editor of the periodical, *Electronics*, which radio workers in Great Britain find so useful in giving them a survey of progress in the United States of the application of electronic devices to radio and other engineering problems.

The television engineer requires a knowledge both of the technique of radio communication at ultra high frequencies, and of the optical problems involved in analysing a picture or scene at the transmitter and rebuilding it at the receiver. Mr. Fink deals with the whole subject within this scope. The historical aspects of the television field are wisely ignored, and a knowledge of fundamental physics and of ordinary radio technique is assumed.

The early chapters of the book deal with the analysis and scanning of the picture, and the principles of the devices used to convert the variations in light intensity into electric impulses. Following chapters describe the nature of these impulses forming the video signal, which after amplification provides the modulation of the radio frequency carrier waves broadcast to the distant receivers. At the receiving end the process is reversed, and the modulation signals are extracted in order to provide the impulses necessary to reproduce the picture on the screen of the cathode ray tube in the receiver. All these subjects are dealt with in a clear and thorough manner, and references are given, mostly but not entirely, to American literature, which will enable the reader to delve deeper into any aspect of the subject in which he is particularly interested.

The last two chapters in the book deal with the practice of television broadcasting in the United States from studio to transmitter, and of the design and construction of receivers. These, together with the appendix, which sets out the nomenclature, standards, and recommended practices drawn up by the American Radio Manufacturers' Association, should make the whole work of considerable value to engineers responsible for the development and expansion of television throughout the world. The production of this volume is quite in accordance with the very high standard normally attained by the publishers.

Textile Testing

Physical, Chemical and Microscopical. By Prof. John H. Skinkle. Pp. x+272. (London: Macmillan and Co., Ltd., 1940.) 15*s*. net.

PROF. SKINKLE'S book will be welcomed by those engaged in the textile industry as well as by teachers of textile technology. The author has had an ambitious aim. He has endeavoured to cover the physical, chemical and microscopical aspects of textile testing. The microscopical section, which deals with the identification of fibres, might with advantage have been illustrated. The physical section describes all the usual physical tests and, indeed, includes several tests which might not normally be expected in a book of this kind. In the chemical section, the author indicates how fibres, both synthetic and natural, may be related in chemical nature to the carbohydrates and proteins respectively, and he has given standard American methods of analysis of synthetic and natural carbohydrate fibres, and of wool and silk.

While the book in many respects may be regarded as a students' working manual, in others it is more ambitious. It outlines, for example, current conceptions of cellulose, wool and silk structure, and it makes abundant reference to the *Journal of the Textile Institute*, in which much modern textile research is published. The book should certainly make a valuable addition to the textile libraries of Great Britain. It is a pity that the diagrams, as, for example, that of the Soxhlet extraction apparatus on p. 159, are frequently poorly reproduced. In any later edition, attention should be given to this point.

Plant Microtechnique

By Donald Alexander Johansen. (McGraw-Hill Publications in the Botanical Sciences.) Pp. xi+523. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 30*s*.

THE author points out that during the past ten years immense strides have been made in microscopical technique and in our knowledge of life-histories, and the present volume is an attempt to sift the mass of information in the literature and to correlate it so as to be of optimum service to laboratory workers. The book is not intended to be an encyclopædia of methods, but succeeds in giving in a readable form full details of a range of procedures which have been selected as the more reliable and generally useful, as the result of tests carried out in the Stanford laboratories. One of the marked features of modern methods is the tendency to use, wherever possible, whole-mount preparations, maceration and smear methods, and thicker in preference to thinner sections; and such points as these receive full attention. Adequate details are given for the making up of the stains recommended, and many useful hints are included as to the optimum thickness of section, time of day for collecting material for special purposes, etc., which may save much time in preliminary tests. Though the author deals to some extent with reagents of American origin, this is not likely to interfere appreciably with the value of the book to users in Great Britain.

The first section of the book gives a general survey of methods of fixation, staining, microtoming and of more specialized techniques used in cytology, whilst the second and larger section shows how these may be adapted as special methods for the various phyla. It is in dealing with Algæ, Fungi and such lower types, where the constructional substances may differ so widely, that the greatest difficulties are encountered in selecting suitable methods of preservation and examination, and it is probably on such points as these that the book will prove of the greatest value as a reference work, especially as the bibliography may also be used if further details are required.

For each phylum some details are given of the life-cycle, suggestions as to methods of collecting, preservation as herbarium specimens or for laboratory purposes, cultural methods and suitable stains. These details apply not only to the more elementary class types such as Spirogyra, Vaucheria, etc., but also so far as possible to such less-exploited types as the Pyrrophyta, Cyanophyta, Fungi Imperfecti, Lichens, etc. In the higher phyla details of staining, thickness of sections for embryo sacs of Gymnosperms and Angiosperms, methods for germinating pollen grains, etc., also include very numerous hints which should prove of the greatest value.

Industrial Solvents

By Ibert Mellan. Pp. xi+480. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1939.) 66*s*. net.

THIS is a mine of information; in it may be found the fungicidal action of diacetin, the intensity of the smell of isobutyl mercaptan, the solubility of nitrocellulose in ternary mixtures, and a vast amount of miscellaneous data which it would be exceedingly difficult to locate in the literature. Even in the book itself, the path is not always clear; a table of dielectric constants appears in the middle of a chapter on volatility and toxicity, while other tables and graphs having little or no connexion with the text crop up at intervals. The effect on the reader is the creation of a sense of bewilderment, particularly in the opening chapters, but this is dissipated by the major portion of the work, which is devoted to an excellent account of the properties of some 180 solvents arranged according to their chemical composition. Several pages are allotted to the more important substances and a few lines only to others, but it would seem that very little information has escaped the eye of the author, particularly when solutions of cellulose derivatives are concerned.

After a useful chapter on plasticizers, the book concludes somewhat unexpectedly with a section on graphical expression and interpretation which is so good that the intrusion may be forgiven.

Future editions would be improved by some rearrangement and a more detailed index, but even as it stands, the volume will be found indispensable to every user of solvents. H. E. W.

CYRENAICA: CULTURE AND ANTIQUITIES

ONCE more with the fall of Benghazi and the British occupation of Cyrenaica, the Libyan menace to Egypt is frustrated. For, indeed, the present campaign against the forces of Italy in her North African colonies is but the latest phase in a conflict between the peoples of the Valley of the Nile and the dwellers in the Libyan Desert and on the coastal fringe westward from Egypt, which *mutatis mutandis* has endured intermittently for many a hundred years. So long ago as the thirteenth century B.C., when the Nineteenth Dynasty ruled over Egypt, Pharaoh Menephthah drove back from the Delta the attack of the peoples of the Mediterranean Sea, Achæans and Lycians, Sardinians and Tyrsenians as they are thought to have been, who, in alliance with and under the leadership of Libyan chiefs, sought to overrun the rich lands of the Nile. But such acts of aggression were not entirely one-sided. Long before, under the Twelfth Dynasty, Amenemhat I had sought to extend his empire over Libyan tribes with the object of exacting tribute from the wealth acquired by their control of the caravan routes from the interior. Under the Twenty-second Dynasty the Libyans with Sheshonq, the Shishak of the Bible who besieged Jerusalem, as their first ruler, established a hold over Egypt which endured from 950 until 740 B.C.

That campaigning in Libya in those days was no less strenuous than it was found to be by the British Imperial troops is suggested by the story of the rise to power of Amasis in 572 B.C. His army, when sent on an expedition into Libya, was convinced that it was intended that they should all perish. They rebelled and raised Amasis to the supreme power, displacing Hophra, the ruling monarch.

Since the Italian occupation, the term 'Libya' has been applied to the two provinces of Tripolitania and Cyrenaica. In the latter, the eastern province of Cyrenaica, geographical conditions, which have been made in some measure generally familiar by recent events, have had a marked effect on the history and development of culture of the inhabitants. The dominant features are two great plateaux which rise steeply from a narrow coastal strip, and then slope down to the desert, which the more important, Jebel Akhdar, reaches at a distance of some eighty miles. Its heights are well watered with abundant springs and its good red soil grows good crops of barley, while the Arabo-Berber nomad or semi-nomad tribesmen find here pasture for their herds of cattle, sheep and camels.

Little less important in a cultural context is the Augila depression, which runs by a remarkable series of oases from the Gulf of Sidra, the ancient Syrtes, to the regions of the Upper Nile. It has served as a line of communication and path of cultural diffusion for countless ages ; but in recent years its importance as a line of communication with the interior has declined with the opening of the Khartum Railway. Of the oases traversed, Kufra, a group of five at the head of the Libyan Desert, covering some 7,000 square miles, is the most important ; it is best known, perhaps, on account of the Senussi sect of Moslems, founded in the nineteenth century, who had their headquarters here until in 1928 the Italians occupied the interior, driving them back to the oasis of Jaghbub then recently ceded from Egypt. Of special interest to archæologists is the "lost" oasis of Oueinat, reached by A. M. Hassanein Bey in 1923, where were discovered some remarkable series of rock paintings and drawings which have since been the subject of considerable study and speculation.

The modern indigenous population of Cyrenaica, since the Arab conquest of A.D. 641, is Arabo-Berber, an amalgam in which the Berber tongue has virtually disappeared along with the script which, as inscriptions show, had been evolved but now survives only among the Masked Tuareg of the western Sahara. Physically, the population belongs mainly to the North African type of the Mediterranean race. Indeed, among the theories of derivation of the North African Berber as found farther to the west, one would assign them to an origin in Libya. In their origins the people of Libya would appear basically to have been closely akin to the proto- or pre-dynastic Egyptians, if reliance is to be placed upon the scanty human skeletal remains which have been found and examined, notably at Mersa Matruh.

Archæological evidence may well be regarded as bearing out a close relation with Egypt in early times. Finds of palæoliths of Mousterian type similar to those of Egypt would seem to confirm this view. On the other hand, more intensive exploration and study, such as the Stone Age has received in French North Africa and has been given by Miss Caton-Thompson to the Stone Age cultures of Khargeh, may reveal links by which Libya will be joined in a North African palæolithic complex. In the meantime, for later ages from mesolithic times onward, detailed study of the Oueinat pictographs has not only revealed evidence of a cultural, even possibly a racial, sequence, but also in conjunction with other evidence the possibility of a connexion with north-west Africa, going back to neolithic or even mesolithic times, and of a diffusion of culture from the upper regions of the Nile which must have traversed Libya by the desert-oasis route and cannot fail to have had its cultural effect on the way.

Up to the middle of the nineteenth century, knowledge of Cyrene and the Pentapolis was confined almost exclusively to literary sources. From Herodotus, we learned of its foundation by Battos, its first ruler, as a colony from Therae, in accordance with the behest of the Delphic oracle, after a misunderstanding of the instruction that it should stand "between the waters" had led to an abortive settlement on the island of Plataea in the Gulf of Bomba. This took place in the middle of the seventh century B.C. The city, which was then built on the high ground in the midst of springs, and appropriately and of right was dedicated to Phœbus Apollo, grew to be the greatest of Greek colonies, with Apollonia as its port, after it adopted a constitution framed by Demonax of Mantinea. This constitution divided the people into three tribes and determined the hostility between Greeks and Libyans, which had previously prevailed and which the intervention of Amasis for the Libyans had failed to compose.

The foundation of Cyrene was followed first by that of Barca, then of Hesperides-Berenice (Benghazi) and Arsinoe, with Apollonia making up the five cities of the Pentapolis. Derna (Darnis-Zarine) was a later Ptolemaic foundation. Cyrene, after a period of great prosperity due to commerce, in which at one time the city attained a population of 100,000, was the home of the Cyrenaic post-Socratic school of philosophy: it declined under the Ptolemies, to whom it had fallen as a result of its submission to Alexander in 331 B.C. Trade between Egypt and Carthage, upon which its prosperity had largely depended, was then diverted to the more direct route through Barca. Towards the close of the Ptolemaic rule, Apian gave Cyrenaica to Rome by his will and, with Crete, it was formed into a Roman province. It now had a large Jewish population, but disorders among them in both Barca and Cyrene under Hadrian brought about a complete eclipse in favour of Apollonia in A.D. 115–16. The two cities revived under Arab rule and for some time thrived on the trade between Alexandria and Qairwan, to fall with the remainder of the province into obscurity and disorder when the Ottoman Turks came into power.

In certain respects the fate of Cyrene and its decline under the Ptolemies and its later Roman masters was a piece of good fortune for posterity. Alone among archæological sites of Greek origin of any importance in Roman North Africa, it preserves its early form virtually untouched by Roman magnificence. The state of preservation of the *temenos*, or sacred enclosure, is unique. Here two baths only were introduced by the Romans. Nothing was known of the antiquities of Cyrene until it was visited in 1861 by two English officers on leave from Malta, R. Murdock Smith and E. A. Porcher, by whom the dedicatory temple of Apollo was identified and a number of antiquities retrieved which were afterwards sent to the British Museum. The next exploration of any note was by an American expedition, and was directed to the excavation of the Acropolis. This began in 1910, but ceased when Cyrenaica was taken over by the Italians in 1912. Since then, excavations have been carried out more or less systematically by the Italians, and with some enthusiasm since 1928, when the Fascist colonial policy in Africa had assumed more highly colourful aims in the revival of the glories of the Roman Empire. The archæological finds from the excavations at Cyrene are deposited in the Museum at Benghazi, with the exception of the Aphrodite Anadyomene, which is in Rome.

The original foundation of the acropolis of Cyrene stands on the western of two hills. In the valley between them and climbing the south-western slopes of the eastern hill lies the town. The acropolis is surrounded by a wall. Outside on the north is the sanctuary of Apollo, below the sacred fountain Kyra. This spring issues through a portico from a tunnel artificially enlarged. Its course upward can be followed for three to four hundred yards, the walls being freely inscribed by visitors. The sacred precinct presents a new feature in Roman Africa, in that the underlying Greek plan can be readily followed. In it are the temples of Artemis and Apollo, each with a large altar standing before it. That before the temple of Apollo is twenty-three yards long. A remarkable feature of the temple of Artemis is a Nymphæum, which possibly may have been used for purificatory rites. In the floor of the temple of Apollo treasure cists have been found. The original temple erected by Battos I was reconstructed under Augustus, and a further reconstruction was carried out under (possibly) Hadrian, but the original plan is still to be discerned. Subsidiary temples, a Greek theatre, and Roman baths are within the *temenos* walls, which are entered by Roman propylæa. Some twenty marble statues have been brought to light on this part of the site. Among the more remarkable finds from the eastern hill is a fine head of Zeus of Pheidian type, showing a trace of gilding, to which a head of Poseidon forms a pendant.

A striking feature of the plan of the site is the Sacred Way, which lead from the sanctuary past the sacred fountain to the Agora. This latter is a colonnaded area of the conventional Roman type, with its capitol and official buildings. Here, however, are also survivals from the Greek period, the Heroon and the tomb of Battos.

To most of those, however, who have visited ancient Cyrene, the most impressive spectacle has been the vast array of tombs which line the Sacred Way along the road from Cyrene to Apollonia. They vary in size and dignity from the simple cist. with its slab cover, to the elaborate and stately façade which admits to one or more halls or chambers in which the burials lie in pits in the floor and in recesses. A few wall paintings survive, for the most part representing some form of funeral games. Participants, all in Greek dress, are both black and white in colour. Presumably, therefore, as under the constitution of Demonax in civic matters, so in ritual, Greeks and indigenes ignored the colour line.

RICKETS, CALCIUM AND CEREALS

THAT consumption of cereals may in certain circumstances lead to the appearance of rickets was first shown in 1920, when E. Mellanby[1] found that increasing the amount of them in the diet of young animals that were deficient in the antirachitic vitamin increased the intensity of rickets. Mellanby at first supposed that cereals increased the rate of growth of animals, and therefore increased the demand for the food factors necessary for the calcification of the bones and teeth. But his later experiments showed that cereals could be graded in their rachitogenic effect, oatmeal being very potent, and wholemeal wheat flour being more rachitogenic than white flour; yet the cereals with the largest amount of calcium and phosphorus, such as oatmeal and wholemeal flour, tended to cause the lowest retention of these elements in the bones and teeth. Mellanby supposed that these cereals contained an active rachitogenic substance, and this view was strengthened by his observation[2] that the effect could be destroyed by boiling the cereal with dilute hydrochloric acid. He further showed that the rachitogenic effect of cereals could be completely antagonized by adding sufficient vitamin D to the diet, and that it could be largely antagonized by adding calcium carbonate or phosphate.

In the course of her experiments on diet and the teeth, M. Mellanby[3] showed that germination of oats did not affect their anticalcifying action, but this action was greatly diminished if they were ground and allowed to stand for two days. She considered that the destruction might be due to enzyme changes or to the production of vitamin D. Templin and Steenbock[4], however, found that the disappearance of the rachitogenic action of maize, when it was germinated and autolysed, was accompanied by a change of its organic phosphorus to the inorganic form. Steenbock *et al.*[5] had previously suggested that inorganic phosphorus added to the diet might not be equivalent in physiological properties to the organic phosphorus in cereals; their experiments certainly demonstrate the fact that inequality of phosphorus intake is not the sole reason for the difference in calcifying action of the various cereals.

Steenbock's suggestion that the phosphorus compounds of cereals differ in their biological availability was followed up by Bruce and Callow[6]. Most cereals are rich in phosphorus, but 50-80 per cent is present in the form of phytin-phosphorus, phytin being the calcium-magnesium salt of phytic acid (inositolhexaphosphoric acid). Using rats on diets high in calcium and low in phosphorus and vitamin D, Bruce and Callow showed that the rachitogenic effect of cereals could be explained by the low availability of phytic acid phosphorus. This form of phosphorus was also shown to be comparatively unavailable to man (McCance and Widdowson[7]). Bruce and Callow further stated that when deficiency of calcium was the factor limiting calcification, there were grounds for believing that excess of phytic acid would interfere with the absorption of calcium; and Starkenstein[8] had shown that calcium phytate was insoluble or non-ionized. Mottram and Palmer[9] concluded that the rachitogenic action of cereals is not specific, but is due to their unbalanced calcium-phosphorus ratio. But the more extensive work of Lowe and Steenbock[10] had shown that not only the ratio of calcium to phosphorus, but also the proportion of the latter present in the phytin of cereal, determined its rachitogenic potency; they found that phytin phosphorus was partially available to the rat when the diet was low in calcium, but that the addition of calcium carbonate made it almost completely unavailable.

Mellanby, however, considered that these experiments on the relative availability of phosphorus in different compounds had little direct bearing on the positive rachitogenic action of cereals which he had described. He had found that, under his experimental conditions, the addition of inorganic phosphorus produced no improvement in calcification, and the dietary conditions in his experiments with puppies approached much more closely the conditions leading to rickets in children (which is not usually affected by adding inorganic phosphorus to the diet) than did the experiments of Bruce and Callow using rats on diets high in calcium and low in phosphorus. But their suggestion that phytic acid interfered with the absorption of calcium was directly relevant, and was followed up by Harrison and Mellanby[11]. These workers found that phytic acid and neutral sodium phytate were strongly rachitogenic when given with a non-rachitogenic diet; commercial phytin was slightly antirachitic. They concluded that "while our experiments do not support the view that the non-availability of phytic acid phosphorus has anything to do with the anticalcifying action of cereals under physiological conditions, they do strongly suggest that this anticalcifying action of cereals is due to the action of phytic acid in rendering Ca unavailable". On this view, further amounts of calcium will be used for calcification only after all the phytic acid has been precipitated, and therefore, since wholemeal flour contains more phytic acid than white, it is necessary to add more calcium to the former.

The antirachitic action of phytin was noted by E. Mellanby[12] and later by Palmer and Mottram[13]. De Bruin and Bouman[14] had concluded that the phytin content was not the cause of the rachitogenic action of cereals, and Harris and Bunker[15] had found no direct relationship between the amount of phytin phosphorus in cereals and their rachitogenic potency. These apparent anomalies were answered by Harrison and Mellanby. They suggest, for example, that in the gut commercial phytin (which is rich in calcium) might lose some calcium, which is replaced by magnesium or other bases, and this liberated calcium then might be slightly antirachitic.

The recent work of Steenbock and his colleagues[16] has shown that the whole tale of the rachitogenic action of cereals has not yet been told. Rats were given a diet containing no cereals, normal calcium and low phosphorus. Some phytic acid phosphorus was available even without vitamin D, but much more when the vitamin was given. This effect was less marked with inorganic phosphorus, and in no case was the utilization of phytic acid phosphorus equal to that of inorganic phosphorus. In other experiments[17], it was found that when calcium phytate was added to a diet containing no cereals and low in calcium, its calcium was as readily available to the rat as the calcium of calcium carbonate. Vitamin D improved the utilization of both forms of calcium to the same extent.

Recently, the same workers[18] have found that the availability of the phytic acid phosphorus was affected by the calcium-phosphorus ratio of the diet. With an optimum intake of phosphorus and a ratio of 1, phytic acid phosphorus was almost as readily utilized as the inorganic form. An increase in the ratio was accompanied by a marked decrease in the availability of phytic acid phosphorus but not of inorganic phosphorus; the ratio is of no great importance when the phosphorus is present in the inorganic form. Day[19] has shown that citrates promote calcification when given with a cereal diet containing high calcium and low phosphorus, but not when given with a purified diet; they have no effect on calcification when the calcium-phosphorus ratio is normal or low, irrespective of whether cereals are added. The cereal can be replaced by phytin with similar results.

At a recent meeting of the Physiological Society (Cambridge, December 1940), Sir Edward Mellanby gave an account of his work on the rachitogenic effect of oats, and Dr. R. A. McCance and Miss E. M. Widdowson briefly mentioned some recent results that they have obtained. Further, Steenbock and his colleagues[17] have promised to give consideration in a forthcoming paper to Mellanby's view that phytic acid acts by making calcium unavailable.

It is obvious, therefore, that a final judgment upon the rachitogenic effect of cereals must be suspended. But there can be no doubt that the addition of calcium to white flour, and particularly to wholemeal flour, overcomes the rachitogenic action of these cereals.

There is one aspect of the addition of calcium to flour that seems to have received no attention. Kletzein[20] showed that adding 1 per cent of calcium carbonate to the diet of rats diminished the iron content of their tissues (except the spleen). He further concluded: "That the retention of copper is affected by calcium supplementation in a manner similar to that of iron is suggested by other unpublished data of ours. The association of deficiencies of other minor inorganic elements such as iodine, manganese, cobalt, zinc and boron with excessive supplementation is suggested". Independently, Tompsett[21] has shown that both iron and copper are absorbed more easily on a low calcium than on a high calcium diet. From Tompsett's figures, it seems that increasing the calcium in the diet about sixteen-fold decreases the body iron about 35 per cent. A rough calculation based on the amounts contemplated by Moran and Drummond[22] suggests that the calcium intake of Orr's lowest income group may be nearly doubled by the addition of calcium to white flour. This is, of course, a very much lower increase than that used by Kletzein and Tompsett in their experiments. Certainly, this is no argument against adding calcium to the diet to combat the widespread deficiency of that element in our population; but merely correcting that fault perhaps makes it more important to combat also the deficiency of iron, which is possibly even more serious.

A LIEBIG CENTENARY

IN the autumn of 1840, just over one hundred years ago, there was published in England and Germany Liebig's famous book on "Organic Chemistry in its Applications to Agriculture and Physiology", which was destined to exert a profound influence on agricultural science and practice. It formed part of a report which, in 1837, the author had undertaken to write on the state of organic chemistry for the Chemical Section of the British Association for the Advancement of Science, and the English edition was "edited from the manuscript of the author" by Lyon Playfair, who presumably also translated it. Part 1 of this book deals with "the chemical processes in the nutrition of vegetables", and the shorter Part 2 with "the chemical processes of fermentation, decay, and putrefaction".

In treating these subjects almost entirely from the chemical aspect, Liebig followed in the wake of Humphry Davy, whom he calls "the immortal author of the Agricultural Chemistry", for Davy had there written:

> "If land be unproductive, and a system of ameliorating it is to be attempted, the sure method of attaining the object is by determining the cause of the sterility, which must necessarily depend upon some defect in the constitution of the soil, which may be easily discovered by chemical analysis."

Liebig adopted this view, but went further; in the preface to the third edition of his book (1847), he wrote:

> "Now that the conditions which render the soil productive and capable of affording support to plants are ascertained, it cannot well be denied that from Chemistry alone further progress in Agriculture is to be expected."

There was 'nothing like leather' for these distinguished chemists, and for many decades thereafter agricultural instruction in universities was undertaken as a branch of chemistry. The exaggerated importance of chemistry to agriculture at that time is quite understandable, for the science of microbiology did not exist, the nature of plant diseases and pests was virtually unknown, and no systematic attempt had been made to apply physics to agriculture. It was also due to the lack of biological knowledge that Liebig attempted to explain the phenomena of fermentation and putrefaction in terms of pure, if rather nebulous, chemistry: "whenever the way seemed long, or his heart began to fail" he would invoke such metaphysical entities as "the vital principle", *vis inertiæ*, etc., thus attempting to explain the unknown in terms of a greater unknown. The two outstanding merits of Liebig's book were that it applied, in a manner more complete than Davy and von Thaer had done, the torch of science to the unilluminated mass of facts which empirical practice had accumulated through the ages, and it laid on solid foundations the principle and practice of restoring to the soil certain nutrient elements which had been removed by previous crops.

Liebig was the first to throw light on the nature and functions of soil humus. He did not get very far, but it is doubtful if modern chemists have got very much further. He recognized that the humus of plant physiologists and of chemists is no single chemical individual: the soil humus he defined as "woody fibre in a state of decay". He refuted the widely prevailing view that plants draw sustenance from soil humus other than the carbon dioxide disengaged in its decay, but he held that this action proceeds only in presence of growing plants, so that bare fallowing does not deprive a soil of humus; and that crop cultivation does not deplete the soil of humus, because this is regenerated by the organic substances excreted by plants through their roots. He laid much stress on these excretions or excrements, though he could adduce very little, if any, evidence of their existence.

According to Liebig, soil exhaustion is entirely a matter of depletion of mineral salts, chiefly those of the alkali and alkaline-earth metals, and fertility can be restored only by manuring, for example, with mineral fertilizers. He set the fashion in undertaking innumerable analyses of plant ashes, and he seemed to believe that practically every element found in the ash of a plant was necessary to its existence. Hence he devised a number of special manures containing a variety of mineral salts, some of which, such as potassium silicate and common salt, must have been redundant. These manures were a failure; farmers would have none of them. Though it is easy to criticize Liebig in the light of modern knowledge, one cannot help remarking on his failure to appreciate the nutrient reserves which nearly all soils contain in varying amounts, the availability of the added nutrients when incorporated in the soil, and the percentage recovery of them in the crop.

Foremost among Liebig's achievements in this direction was his recognition of the value of phosphatic and potassic manuring. He is usually, and probably correctly, regarded as the discoverer of the value of 'super' (superphosphate of lime) in the form of dissolved bones, for the preparation of which he gives a recipe in his book. It is true that Escher had already suggested the idea in 1835, and that during 1837–39 Lawes had performed many pot experiments with spent animal charcoal that had been treated with sulphuric acid (although there is apparently no written record of this work), but the idea could not have fructified without the work of Liebig. On the other hand, to Lawes must be ascribed priority in the preparation of superphosphate by treating mineral phosphates with sulphuric acid.

To the student of agriculture, Liebig is probably best known from his long-continued controversy with Lawes and Gilbert concerning how plants obtain their nitrogen. In the first edition of his book, Liebig wrote: "Cultivated plants receive the same quantity of nitrogen from atmosphere as trees, shrubs, and other wild plants; *but this is not sufficient for the purposes of agriculture*". In the fourth edition he altered the latter portion of the sentence to "*and this is quite sufficient for the purposes of agriculture*" (the italics are the writer's). Elsewhere, in both editions, he states that decaying nitrogenous organic matter contributes in a minor degree to the nitrogen supply of plants. Thus he shifted his ground; but his main contention was that atmospheric ammonia, originating in the decay of vegetable and animal substances, was the prime source of the nitrogen supply of plants. He was at some pains to explain how the ammonia (the amount of which in the air and rain water he over-estimated) became fixed in the soil, as both it and ammonium carbonate readily volatilize. He therefore postulated that minerals containing alumina, that is, clays, and iron have a great attraction for ammonia, readily combining with it and fixing it. He also asserted that humus and added charcoal act similarly. Lawes and Gilbert, in their classical experiments at Rothamsted, proved that the main source of the supply of nitrogen to plants was nitrogenous substances naturally present in, or added to, the soil. There was, of course, at that time no knowledge of nitrogen-fixing bacteria, either 'nodule' or free-living. The result of the controversy, besides settling the main point at issue, provided the scientific basis for nitrogenous manuring.

Great as were Liebig's achievements in wedding science to practice and in establishing the value of mineral manuring, it is open to question whether his chief title to fame does not rest upon his purely chemical discoveries; in any event his combustion-tube and potash-bulbs bid fair to attain immortality. One cannot agree with the dictum of A. W. Hofmann, in his Faraday Lecture to the Chemical Society in 1875, that he and Faraday were "stars of co-equal lustre", but one can stand in admiration of his intellectual ability, of his great success in establishing the first really educational laboratory at Giessen, which attracted students from many parts of the world, and of his striking personality. As a man of science, he was at times "rash in his speculations, hasty in his conclusions, and bitter in his controversies" (Odling), but in the social sphere he seems to have possessed all the virtues. Much of his success was probably due to his personality: he possessed the deep convictions and inner fire of a *Führer*, not one of the ultra-nationalistic type, but one who, at least in scientific matters, was a cosmopolitan at heart. At the same time he would doubtless have been ready to subscribe to the dictum of Pasteur, "*La science n'a pas de patrie, mais les savants en ont une*".

E. H. T.

OBITUARIES

Dr. Alfred Young, F.R.S.

ALFRED YOUNG, the fifth son of Edward Young of Birchfield, Farnworth, a prosperous Liverpool merchant of his time, was born in 1873 and died on December 19, 1940. His death is a loss not only to the parish of Birdbrook, where he was rector, and to many friends, but also to the wider scientific world in which as a pure mathematician he had won a distinguished place.

Educated at Monckton Combe School, Young gained a scholarship in mathematics at Clare College, Cambridge, which he entered in 1892. It was there that I first met him and began a friendship which continued throughout his life. As an undergraduate he took part quietly in the ordinary social and athletic life of the College. A pupil of the celebrated mathematical coach Webb, of St. John's College, he took his B.A. degree in 1895, being bracketed 10th wrangler in a year which included the names of Bromwich, Grace, Whittaker, Hopkinson and Godfrey. It was early in his third year that his interest in research began; his enthusiasm for it diverted him from the subjects laid down for the Tripos examination. His place in the lists would almost certainly have been higher if he had confined his energies to the schedules; undoubtedly, however, he chose the better path.

Young had always intended to take Holy Orders, but it was not until 1908 that he was ordained. In the meantime, he continued his mathematical research; he was the author of many papers in the scientific journals, and collaborated with Grace in "The Algebra of Invariants" published by the Cambridge University Press—the standard work on the subject. For some years he lectured at Selwyn College, but resigned that appointment shortly after his election to a fellowship at Clare in 1904. His work received recognition when in 1908 he was accepted for the degree of Sc.D. at Cambridge, in 1931 when he became honorary LL.D. of St. Andrews, and further in 1934 when he was elected a fellow of the Royal Society. This latter honour he shared with his elder brother Sydney Young, professor of mathematics at Trinity College, Dublin. Prof. H. W. Turnbull tells me that "as Young developed his method of Quantitative Substitutional Analysis he was led to the study of the Theory of Finite Groups of which Burnside and Frobenius were the leading exponents. In Group Theory Young was a worthy successor to Burnside; as an algebraist he stood in the front line, and in sheer algebraical manipulation he possessed an insight which can only be described as uncanny".

Young served after his ordination for two years as a curate of Christchurch, Blacklands, and was then presented by his College to the rectory of Birdbrook. His good work as a parish priest led to his appointment in 1923 to the rural deanery of Belchamp and to an honorary canonry at Chelmsford shortly before his death. He was an excellent preacher; a sermon of his at the Commemoration of Benefactors at Clare stood out among many such discourses to which I have listened, as admirable both in substance and in style.

Young had a quiet humour. I remember an occasion when he said to me with a grave face: "I have lost all sense of personal security". It appeared that the maidservant at his Cambridge lodgings had used some of his manuscripts to light the fire rather than waste clean paper for that purpose.

He was married in 1907 to Edith, daughter of Edward Wilson of Eccleshall, by whom he is survived. There were no children of the marriage.

G. H. A. Wilson.

Dr. G. E. Vincent

The last public appearance in London of Dr. George Edgar Vincent, president of the Rockefeller Foundation from 1917 until 1929, who died in New York on February 1, was at a luncheon given to him at the Criterion Restaurant on May 18, 1932, by the English-Speaking Union. He was a tall bronzed man of sturdy figure, expressive in countenance and eager-eyed. Talking upon the broad subject of international philanthropy in international relations, Vincent revealed himself as an amiable and persuasive character, more French than Anglo-Saxon in the rapidity and preciseness of his thoughts, as if he feared he would have not quite time enough to say all he wanted to say. It was clear to his audience that here was a man who in his day had convinced many listeners, both individual and collective.

Vincent was born in Illinois, but like many middle-westerners of the abler sort, was educated at Yale. Returning to Chicago, he taught sociology in its university. In the long vacations he joined the Chantanqua Institution, which gave lectures upon literary and scientific subjects, lectures held in tents, in many parts of the country. This varied experience with students well fitted Vincent to become Dean at Chicago (1907), then president of the neighbouring University of Minnesota (1911). His first connexion with charitable trusts was three years later; he joined the General Education Board, endowed not long before to assist American universities.

But at Minnesota, where he continued, Vincent put a strong hand to the expansion of its post-graduate schools of law, medicine, chemistry, engineering, and agriculture. Minnesota is one of the richest of American western universities, which draws large income from copper mines owned near Lake Superior, and Vincent, with such backing, found his opportunity. Meanwhile, so impressive was the counsel which he was offering to the General Education Board, that in the midst of the last war, in 1917, he was invited to the presidency of the Rockefeller Foundation.

Vincent had long been distressed over the meagreness of academic salaries. Many abler young graduates avoided teaching for more lucrative careers. He therefore strongly advocated, as soon as the War of 1914–18 ended, a distribution of £2,000,000 to endow and increase salaries of American university staff. This was the scheme under which the Rockefellers added a dollar to every dollar raised for that purpose by any well-established university or college. In the end 170 of them participated.

At this period the Foundation, under Vincent's leadership, was making large benefactions to medical education. It was particularly interested in China. Vincent, after leaving Yale, had travelled in the Orient, and his advice in respect of the support of Peiping Union Medical College was invaluable. Again, a signal gift under his regime was £500,000 for the London School of Hygiene and Tropical Medicine.

Vincent's final activities up to his retirement in 1929 included organizing for the Rockefellers the division of social sciences, in which he was a specialist, and the divisions of natural sciences and international health. WILLARD CONNELY.

Prof. B. P. Haigh, M.B.E.

BERNARD PARKER HAIGH, professor of applied mechanics in the Royal Naval College, Greenwich, who died on January 18, was born in 1884. Educated at Allan Glen's School, Glasgow, and afterwards at the University, he was apprenticed to Bruce Peeples, electrical engineers in Edinburgh, where he worked under J. L. la Cour, the inventor of the rotary converter which bears his name. This association took Haigh to Germany and to Sweden, where he obtained much valuable experience. From 1909 he was engaged for two years on the design of steering gears at the Edinburgh firm of Brown Bros., and then became assistant to Prof. Archibald Barr at the University of Glasgow. It was in 1913 that Haigh took the step which was to determine his career, when he became lecturer in applied mechanics at the Royal Naval College, where he succeeded in 1920 to the chair left vacant when Sir James Henderson retired in order to give his whole time to gunnery problems.

At Greenwich, Haigh found himself immediately confronted with a variety of new problems connected with the Royal Navy. He became a scientific adviser to the Paravane Department of the Admiralty. Of his successful work in this connexion, the solution of the problem of lengthening the life of the steel ropes which towed the paravanes in their duty of cutting the moorings of mines may be mentioned. Haigh considered that the very short life of these ropes was due to fatigue caused by resonance brought about by synchronization between the natural periods of vibration of the rope under tension and the eddies thrown off by the rope as it passed through the water. He deduced a formula and was able to increase considerably the life of the ropes. During this investigation Haigh realized, about 1917, that fatigue was greatly accelerated in steels when it takes place in the presence of a chemical reagent. He likewise established that corrosion prior to fatigue has but little effect on the fatigue limit. These were new discoveries of fundamental importance. The phenomena were rediscovered some ten years later by McAdam and are now popularly known as 'corrosion fatigue', a terminology of which Haigh strongly disapproved on account of the second fact mentioned above. These discoveries accentuated the interest which Haigh had taken, from his student days, in fatigue of metals, and on this matter he became a recognized authority both here and abroad. A large part of Haigh's published work is directly inspired by ideas connected with fatigue, although he wrote many papers on plasticity, welding, fracture and allied topics. He was also the inventor of the Haigh fatigue testing machines which are internationally used in experimental laboratories. Much of his work was of a confidential nature, and he was always busy with some Admiralty problem.

Apart from this Haigh was a very active participator in general scientific affairs. He attended the International Congresses for Applied Mechanics and was present at the recent World Power Congress in America. He was also a member of the British Association Committee on Stress Distribution in Engineering Materials and read several papers before the Association.

At the beginning of the present War, Haigh was selected as scientific adviser to the Engineering Research Laboratory of the Admiralty. At the funeral service in the Chapel of the Royal Naval College, the Chaplain of the Fleet in his encomium stated that Haigh had suggested and helped to perfect the method of overcoming the magnetic mine.

To appreciate Haigh's enormous energy it must be remembered that these activities were in addition to his teaching duties. In teaching as elsewhere Haigh was eminently successful, for he had an unrivalled gift of communicating his own enthusiasm for his subject and a quite uncommon knack of choosing happy and apt phraseology. His loss will therefore be felt by the many Naval officers who have been instructed by him, as well as by his colleagues at the Royal Naval College, who found in him loyalty and friendship.

Haigh married, in 1915, Mildred Cole. They have one son, Ian, who is now on the staff of Sir Alexander Gibb. L. M. MILNE-THOMSON.

Mr. H. W. Macrosty, O.B.E.

MR. H. W. MACROSTY, president of the Royal Statistical Society, died at his home at Woking on January 19. Mr. Macrosty had been an honorary secretary of the Society for twelve years prior to his election as president in June last. His interest in statistics was derived from his official duties in the Board of Trade, where he was prominently associated with the work on the national census of production from its inception in 1907. His work was essentially that of providing data for economists and statisticians and in providing critical comment on those data. This did not bring him into the limelight which is shed upon those who announce policies or enunciate economic propositions, but as a contribution to national service such work is in no way less important than that of those who come more prominently to public attention. Only those statisticians with practical contact with industry and trade can properly appreciate the true value of the work of those who produce statistical data.

It was the great merit of Macrosty and his co-workers at the Board of Trade that they concentrated upon accuracy and reliability in the statistical material they collected and which was the basis for the measurement of the industrial production of Great Britain. To the uninitiated a statistical table looks much the same whether drawn up from slipshod material or from data thoroughly sifted and scrutinized. The scrutiny and criticism by the Census of Production Office of the virgin material has been of the greatest importance. As a consequence, it can be truly said that although the volume of official statistical output relating to industry in Great Britain has lagged behind that of a number of others, its quality is such as to afford confidence to those who turn to the various reports for guidance and instruction, and Macrosty played a great part in establishing the confidence felt in the reliability of British official data relating to trade and industry.

To the Royal Statistical Society Macrosty gave unsparingly, both in the capacity of senior honorary secretary for many years and by practical contributions to its *Journal*, while he was the compiler of the attractive volume recording the history of the Society through a hundred years and published at the celebration of its centenary in 1934.

Mr. Eliot Howard

With the death of Eliot Howard on December 26 a distinguished ornithologist has passed away.

Howard was one of the notable amateurs for which British science, and especially perhaps British natural history, has always been distinguished. His professional work was with the firm of Stewart and Lloyd, of which he was a director for a number of years. In spite of this, he kept up his interest in field ornithology and published several important books on the subject. His most extensive work was a monograph on the British warblers (1907–1914), which embodied a great number of new observations made by himself on their habits. These observations, together with others on other types of birds, were generalized in his "Territory in Bird Life" (1920).

Though Howard was not actually the originator of the idea of territory and its importance in the life of birds, it was through his work that its importance became generally realized. He published three later studies, including "An Introduction to the Study of Bird Behaviour" (1929) and "The Nature of a Bird's World" (1935), in which his increasing preoccupation with the philosophical bearing of his observations became evident. Many of his friends perhaps regretted this preoccupation, as in their view it interfered with his publishing the vast body of original observations which he had accumulated on many species of birds. However, ornithologists will be glad to learn that his notes have been left by his widow to the Edward Grey Institute of Field Ornithology at Oxford, where they will be available for students. The Institute now possesses the field notes of all the major British field ornithologists of the last generation—Selous, Coward, Jourdain and Howard.

Howard was an outstanding example of how an amateur worker could achieve results of first-class scientific importance through patience and immense attention to accuracy and personal observation. His death is a great loss to ornithology.

Dr. W. C. Bosanquet

Dr. William Cecil Bosanquet, a distinguished London physician and classical scholar, died on January 24 at the age of seventy-four. He was educated at Eton where he was a King's scholar, at Oxford where he gained a first class in Classical Moderations and Lit.Hum. and was elected a fellow of New College, and at Charing Cross Hospital. He qualified B.M. and D.M.(Oxon.) in 1897, and seven years later was elected a fellow of the Royal College of Physicians, before which he delivered the Goulstonian Lecture in 1905, his subject being "The Nature and Treatment of Diabetes Mellitus". He was physician to Charing Cross Hospital, the Brompton Hospital for Consumption, the Victoria Hospital for Children, and the Lock Hospital. During the War of 1914–18, in which he was Captain and Major in the R.A.M.C., he served as consulting physician in the North Western Frontier Force, India. His literary activity, both as editor and author, was considerable. Besides being editor of the *Practitioner* for some years, he was assistant editor of the third edition of "Quain's Dictionary of Medicine" (1902) and editor of the eleventh (1911) to thirteenth (1923) editions of Green's "Manual of Pathology and Morbid Anatomy". In addition to numerous articles in the *Lancet* and *British Medical Journal*, he was the author of "Serums, Vaccines and Toxins" (1904), in the second and third editions of which Dr. J. W. H. Eyre was his collaborator, "The Stomach, Intestines and Pancreas" with Mr. H. S. Clogg, his surgical colleague at Charing Cross Hospital (1909), and "Spirochætes: A Review of Recent Work with Some Original Observations" (1911). In his last work, written in retirement three years before his death, entitled "Meditatio Medici: a Doctor's Philosophy of Life", he discussed the ancient and modern views of the material universe, the development of man, the physical aspects of consciousness or mind and the principles of voluntary action or conduct.

J. D. Rolleston.

We regret to announce the following deaths:

Eugen Dubois, discoverer of *Pithecanthropus erectus*, on December 16.

Prof. G. Dawes Hicks, F.B.A., emeritus professor of philosophy in University College, London, on February 16, aged seventy-eight.

Dr. A. T. Masterman, F.R.S., formerly superintendent inspector, H.M. Board of Agriculture and Fisheries, on February 10.

NEWS AND VIEWS

University of Birmingham: Annual Report

THE annual report for the session 1939–40 of the vice-chancellor of the University of Birmingham, Dr. Raymond Priestley, contains many points of interest. Two developments of major importance are the institution of family allowances for members of the staff and the introduction of compulsory physical training. Dr. Priestley, believing that the general tendency of social reform is towards the acceptance of the family rather than the individual as the normal financial unit, has long been a convinced advocate of the principle of family allowances, and he considers that universities should lead rather than follow in such matters, once they are convinced that it is right to move. He "does not fear that the introduction of family allowances will substantially delay or permanently affect the overdue improvement in the salary scales of the middle ranks of the University hierarchy where the shoe admittedly pinches most". The system is not ideal, because it cannot take account of dependants other than children, but there appears no way of overcoming this drawback without introducing unworkable complications and opening loop-holes which might be unreasonably exploited. Critics lay stress on the principle of equation of reward to quality of service, and so does Dr. Priestley, but he would measure reward in terms of standard of living rather than in money, and he would not have men penalized for having families. The allowance (confined to members of staff whose salary does not exceed £700 per annum) is at the rate of £25 per annum for every child, undergoing full-time education, up to the age of eighteen years. The allowance for the wage-earning staff is 2*s*. 6*d*. per week for each child up to the age of sixteen years if undergoing full-time education. The scheme has been in operation since February last year.

The second development is compulsory physical training for first-year students of both sexes. Two periods of ¾-hour each week are devoted to this, and the work is regarded as an integral part of the degree course, reasonably regular attendance being required. Classes of exception and individual exemptions are provided for, but the great majority of students are covered by the scheme, which is supplemented by voluntary classes in the later years. It was intended that there should be a compulsory medical examination of all students entering the University; but this is at present impossible owing to war-time demands on the local medical personnel. There is a military option in the form of membership of the Senior Training Corps. Dr. Priestley thinks this measure of compulsion is right and reasonable as a means of securing the fullest development of the student. In the conviction that the University is concerned with the development in its students of a sense of social responsibility, and of character, membership of the Guild of Undergraduates was long ago made compulsory. The universities are supposed to be training the leaders of the future. They will produce better results if they can improve the physique of the students for whom they have to cater.

Warm appreciation is expressed of the foundation by Mr. Charles Brotherton of the Charles Brotherton Trust to benefit six industrial centres, of which Birmingham is one. This University has benefited immediately by the foundation of two post-graduate scholarships (each of £150 a year) in chemistry. The terms of these scholarships include provision for the candidature of graduates of other universities. "The scholarships are therefore a valuable supplement to the still too few aids to circulation of graduates between universities, an objective that should, I believe, be kept in the forefront of any university graduate scholarship and Fellowship policy, but which is too often hampered by the local patriotism of donor and of university." The University buildings have suffered considerably from enemy action, and the damage would have been much greater but for the energetic action of the A.R.P. workers. It is surprising to learn that the extra-mural work of the University has been maintained and even extended.

Pharmaceutical Students and Military Service

WITH reference to the note on the application of the National Service (Armed Forces) Act to six new groups, covering the ages of 18–19 and 37–40, which appeared in NATURE of February 8 (p. 172), it appears that the question of the reservation of medical and dental students irrespective of the stage they may have reached in their studies has been made more comprehensive by the inclusion of students of pharmacy. It is understood that the Pharmaceutical Society is making representations to the appropriate Ministry concerning the future supply of pharmaceutical students. Such students are at present reserved from military service when they have completed two years of training, and the terms are so worded that they prevent newcomers into the pharmaceutical calling from securing reservation before they are qualified. The consequence may be that after the present generation of students has passed their examinations, there may be only women entrants to the profession for the duration of the War. It is hoped to secure a modification of the schedule which will facilitate the maintenance of a reasonable annual intake of students.

The British Museum in War-time

THE removal of the exhibits and the closure of the galleries of the British Museum (Bloomsbury) as a necessary precaution against the hazards of aerial attacks as well as a depleted staff have by no means been allowed to impose complete cessation of all activities connected with the national collections normally housed here. Indeed, even as a place of public interest and resort, the small exhibition of antiquities in the Prehistoric Room reopened in August last and the selection of books, manuscripts, prints and drawings in two ground-floor rooms have proved a considerable attraction for visitors from overseas and others. The exhibition in the Prehistoric Room includes models of prehistoric sites in Britain and a number of small archæological exhibits and photographs, an evolutionary series of European prehistoric tools and weapons of stone and bronze, a series of newly designed labels giving an outline of European prehistory or early history from 550,000 B.C. to the Norman conquest, a small case of Romano-British antiquities, and photographs and other illustrations of the Saxon ship-burial at Sutton Hoo. The exhibits are either duplicates or of little intrinsic value.

Members of the public and archæologists in particular will, however, receive with regret the announcement that one branch of the Museum's work hitherto carried on without modification or interruption will now cease, at least for the time being. The current number of the *British Museum Quarterly* (**14**, 4; 1940) contains an announcement that publication must now cease until after the War. The excellence of the illustrations and the scholarly character of the contributions, especially when they turned aside from description to broader issues raised by the exhibits, have won for this periodical an enduring place in the literature of the studies with which the Museum is concerned.

Rationalists and Current Concepts

THE RATIONALIST ANNUAL for 1941 (London: The Rationalist Press Association, 1940, pp. 86, 1*s*. net) includes, as usual, a number of articles which are calculated to stimulate controversy, even though some of them may appear to have been written with a sub-intention *pour épater le bourgeois*. Dr. Gilbert Murray in "Why Despair of Reason ?" discusses the thesis that the modern psychologists, in diminishing the authority of reason, have played an important part in turning "a decent and humane world into an ill-managed lunatic asylum"; while Sir Peter Chalmers Mitchell in "Religion in Trouble", in citing the Union of Soviet Republics as an example of the inefficacy of prayer, expresses profound admiration for the achievement of that "new force of civilization" in education and public health. From the former as a "capacity-catcher", he looks forward to "an almost colossal contribution to the progress of mankind". In a contribution on the laws of Nature, Prof. J. B. S. Haldane expounds the modern concept of their nature and authority, noting in particular such modification as has been introduced by the recent work of Jeffreys and Milne, summing up in the conclusion that "so far from being laid down by the arbitrary word of a creator, they [natural laws] may prove to be a system as intimately and rationally knit together as the propositions of geometry, and yet changing and evolving with time like the forms of plants and animals."

Of special topical interest is the article by Sir Arthur Keith on "Human Nature: a New Approach to its Study", in which he returns, but from rather a new point of view, to his now familiar argument of the part played by war in the evolutionary development of races and nations. Briefly, his argument here is that the hormones, being responsible for the differential development of racial (physical) characters, the reaction against contact and interference from outside which is characteristic of the group from the most primitive social stage onward, and is the motive force which lies at the root of the impulse to war, is a provision in human nature to preserve the integrity and isolation of the group as a breeding ground for the development of group or racial characters. Man's mental constitution, therefore, in Sir Arthur's view, thus becomes the 'breeder' responsible for race-building. Passing over the question whether he has not here allowed his metaphor from selective breeding to betray him into a false personification of man's mental constitution, it seems illogical that while he admits the continuous development in size and complexity of the social group within which inter-group discords and enmities are eliminated, he turns away from the conception of one single group embracing all mankind throughout which there would be no more war. Is it not possible to ask whether, if *Homo sapiens* is one single species, is the group struggle to perpetuate racial differences necessary to his survival ?

Carnegie Corporation of New York

THE report of the Carnegie Corporation of New York for September 30, 1940, includes the reports of the president and of the treasurer on the Main Endowment Fund and on the British Dominions and Colonies Fund. The report of the president, Mr. F. P. Keppel, points out that the Corporation has for the first time in many years incurred obligations in excess of the current income of the main endowment fund; this is due mainly to the voting of an emergency fund of 750,000 dollars for the Carnegie Institution of Washington, in addition to a grant of 150,000 dollars to make it possible for the Institution to construct a cyclotron, and to a grant of 650,000 dollars for Harvard University for the reorganization of the Dental School, but partly to the continued low interest rate. Other grants made during the year have been in the field of adult education, library interests, the arts, research and publications. Mr. Keppel points out that as yet there has been no appreciable reduction in the total supply of funds available from all sources for education and research in the United States. Steadily increasing opportunities for fundamental research are being provided by commerce and industry; funds from Federal, State and municipal sources are being maintained and probably increased.

Despite the new and compelling calls for emergency relief in the United States and abroad, a strong appeal for a good educational or social purpose has proved effective with individual donors. Mr. Keppel, however, welcomes the growing evidence of what may be termed a conservation movement in cultural philanthropy shown in the co-operative groupings of institutions which hitherto have been competitive. These groupings, which are found all over the United States, are both formal and informal, including both tax-supported and independent institutions, and they are beginning to demonstrate that steps of this character will not only save money, but also definitely improve the service rendered to students and others. The Carnegie Corporation was specifically chartered for the advancement and diffusion of knowledge and understanding. These are the broad purposes of any non-specialized American foundation. Through consultation with experts, as fair a picture as possible is obtained of each proposed inquiry, and of the human qualities of the inquirer or inquirers. The selection of those to be supported is left to the lay judgment of the Board, the decision to be made in terms not only of comparative promise but also of the funds which the Foundation itself may have available and the chances of support from other sources.

Education, the second major channel of productive activity, requires public approval and public understanding. Mr. Keppel considers that the prospect of increasing public interest in this is favourable. Much, however, remains to be done to clear the public mind as to what the public itself requires from education, and what it can reasonably expect, and also to clarify teachers' ideas as to what the processes of formal education can and can not do to affect the social order. Mr. Keppel emphasizes the importance of recognizing the enormous range in the native abilities of different individuals, as well as the failure to make the fullest use of the great body of professionally trained men and women. We must also grasp much more clearly the underlying unity of the educational process as a whole, beginning for each human being with birth and ending only with death. Division of education horizontally into its various stages, and vertically according to subject of study, has its utility, but parallels of latitude and meridians of longitude do not exist on the face of Nature. The present world situation is regarded as a further challenge to the Foundation to justify its place as a social instrument enjoying exemption from taxation and other valuable privileges.

World Affairs

RECENT Oxford Pamphlets on World Affairs (London: Oxford University Press. 3*d*. net each) well maintain the standard of the earlier numbers of the series. Mr. R. W. B. Clarke, writing on "Britain's Blockade", stresses the need for a dynamic strategy. He reviews the position of specific classes of raw materials, the crucial example of which is oil, as well as the problem of the time-factor and finally the question of food supplies, both in the enemy countries and in the occupied territories. He considers that from the summer of 1941 onwards, open weaknesses may begin to develop. Prof. H. A. R. Gibb's pamphlet on "The Arabs" describes the effect of the impact of the West upon the Arab world, from Arabia to Morocco, and the re-awakening of Arab self-consciousness and nationalism. It provides a valuable background in following the campaign in the Western desert, and indicates some of the problems which confront statesmanship when General Wavell's campaign has been successfully concluded. In Pamphlet No. 41, Mr. E. L. Woodward, under the title "The Origins of the War", seeks the deeper causes of the War. These he finds in the hostilities of certain dominant tendencies in German thought to the liberal, humanitarian philosophy and way of life of Western civilization. National Socialism, he insists, "inherited an evil tradition, and unless this tradition is understood it is impossible to realize the deeper causes making for war in Germany. We are fighting for a particular way of life, which already through the sacrifice and energy of past generations has brought us out of barbarism and set us towards a reasonable and humane existence. As long as our opponents accept their Dervish-like submission to an opposite way of life, our good is their evil and their evil our good".

Occupational Guidance

THE United States Department of Education has published a bulletin entitled "Occupational Information and Guidance: Organization and Guidance" by three experts (Washington, D.C. 25 cents). It is heavily written but important, as it begins a guidance series with a "comprehensive and basic statement of its specific functions". It gives the policy of the Office of Education with the Federal assistance which can now be claimed, the scheme as it is working at present, and types of programmes from several States. The movement is fairly new, as it began in Boston in 1909, and has penetrated far enough of late years to be called "national". The technical vocabulary employed is tedious and we select a simpler statement of the idea behind the efforts made. There are, and can be, no "misfit" children. "The child is what education is for. One might as well say that a man does not fit his clothes as to say that the child does not fit the school."

This doctrine demands a very wide appreciation of ways of making a living, and we are glad to see that this freedom is recognized. Modern conditions of competition have led to extensive changes. Retardation in education and "labor turn-over in industry" were discovered about the same time. To-day the secondary school hands over less desirable pupils to the vocational, and such schools increase, while attendance at continuation lessens. The most earnest of educators can be misled by lack of insight, or late development among young people. Napoleon left the school of Brienne for Paris carrying the recommendation that he might possibly become a fair officer of marines, but nothing more. Anthony Trollope, that best of entertainers in later life, was a dull young man. There is another danger about this vocational enthusiasm, that buying and selling and making a good living out of the process may be regarded as the one aim of living. Some years ago a publicist in Great Britain was able to tell a convention that "Business is the highest form of citizenship and advertising is the highest form of business". Does that view make for happiness, when a man is tired of his job, or for the altruism of good citizenship? A superintendent of schools in the largest American city writes of showing a pupil how to be a radio announcer, or a baseball player. What will he do when the voice is gone, or the muscles for hard hitting are relaxed? There are many new jobs to-day, but one old one remains—the use of leisure time.

Education in the United States

Education has the name of being a dull, dismal subject, though it is incessantly concerned with youth, which is in the fine phrase of Pericles the spring of the world. Its exponents are full of its jargon and have not reached the last triumph of writing, which is simplicity. American work is usually too widely documented to be bright. So we welcome as an exception to this heaviness the October numbers of *School Life*, which comes from the U.S. Office of Education (monthly except August and September, 1 dollar a year), and *School and Society*, which is run by the Society for the Advancement of Education (15 cents a copy). Both have a direct touch with the busy world scarcely possible in Great Britain, where there is less interest in vocational education; in the United States it leads to leaflets on poultry as well as on Soviet ideas of instruction. *School Life* includes a letter from the President indicating that it is a patriotic duty to continue normal education, unless required for special war work. Looking ahead, one might say that it is the business of education everywhere to prevent, if possible, the occurrence of another war. An ingenious graph arranged in ascending rows like a typewriter shows with commentary the increases and decreases in various grades of school attendance. "Radio in Schools and Colleges" recognizes that it cannot, alone and unaided, do much more than stimulate. There are no short cuts to learning, except in the optimistic promises of the world of advertisement. Teachers can learn more than pupils, but among the 360 colleges offering radio courses only one in twenty is designed for them.

There are good, long articles in *School and Society* on up-to-date ideas of the educated man, the prospects of education for war, with the mistakes of the past, on which, we note, all are not agreed, and the world the high school has to face to-day. A letter on "The Teacher's Professional Life" suggests that he should attend conventions, where he can exchange views about his 'shop'. It is important also that he should not confine himself to going about with other teachers and lose touch with the rapidly changing world which supplies his pupils and challenges him to produce good results for democracy. A plea for a better vocabulary among college seniors is interesting. But a "planned, concerted drive" may be less effective than good example, which leads to a tradition of using language carefully and well. A mark of the good speaker is his choice of adjectives.

British Electrical and Allied Industries Research Association

The twentieth annual general meeting of this Association was held on February 14, when the annual report was presented. In a foreword written by the chairman of the council, Mr. C. W. Marshall, of the Central Electricity Board, many interesting remarks about research are made. He points out that research is rarely spectacular to the layman; but owing to the steadily increasing importance to the industry of the activities of the E.R.A., it is now widely appreciated. Mr. Marshall said he has followed the development of the Association from its inception, especially in its relation to electricity supply. Three classes of investigation pursued in the Association's laboratories and elsewhere have been of special interest to him because of their vital importance to the electrical welfare of Great Britain: these are the investigations into circuit-making and breaking, surge phenomena, and properties of insulation.

The search for the most effective and economical types of circuit-breaker has been one of the most difficult and interesting investigations in the history of electrical engineering. To-day, the essential basic phenomena are well understood, at least by switchgear specialists, and circuit-breakers which are to all intents and purposes free from the formerly dreaded fire and explosion risks are available for all applications. The E.R.A. has played a leading part in this development. Lightning research has been a less urgent matter because of the comparatively small incidence of lightning faults in Great Britain. It was nevertheless appreciated that these faults had to be eliminated, and a systematic scheme of investigation was drawn up several years ago. An important stage of the work will be marked by the publication in due course of an E.R.A. compendium of information on surge phenomena, and by the introduction of a commercial model of the E.R.A. surge filter for protecting electrical equipment against damage from lightning. E.R.A. investigations into the properties of electrical insulating materials are helping to make the fundamental discoveries of atomic physicists available to the practical electrical engineer.

Rocket Flight to the Moon

Conditions of life on this earth may turn the thoughts of the escapist to contemplation of other heavenly bodies. For nearness, the moon has much to commend it. The problem of the means of transport still remains. If rocket flight be chosen, J. W. Campbell's recent paper (*Philosophical Magazine*, January 1941) will be found to give considerable help. Special attention is given to the type of flight in which the observer moves with a massive body from which rockets are fired at intervals in directions suitably controlled to guide the main body. Assuming an initial velocity more than twice that of the present muzzle velocity of artillery shells (2500 ft./sec.), a calculation is made of the *minimum* mass of the moving "rocket ship". The result is 2×10^{-9} of the earth's mass. If the mass were distributed as a homogeneous sphere of material of density about that of surface rock (3·3), then the radius of the sphere would be about 2·74 miles. Relevant factors, such as the atmospheric resistance and the control of direction, have been neglected. If they were taken into account, the initial mass would be still greater. On these calculations the rocket ship would be more than five miles in diameter, and would be as massive as Mount Everest.

Mammals and Man

WITH the view of adding definiteness to the rather vague popular ideas of the class of mammals, the Zoology Department of the National Museum of Wales has set up a temporary series of exhibits for which a descriptive pamphlet, "Mammals and Man", has been written by the keeper of the Department, Colin Matheson (pp. 22. 3*d*.). The exhibits show representatives of the main groups of mammals, and indicate some of the ways in which mammals contribute to the welfare of humanity. Thus it is pointed out that of 3,500 known species of mammals, only about twenty have been thoroughly domesticated, and some of the breeds of the most familiar animals are illustrated among the exhibits. The economic products of the group are represented by wools of various kinds, by furs, particularly dressed furs made from rabbit skins, leather, many products of bones, food materials and so on. The arrangement follows the economic zoology which was a popular diversion of last century, but we miss references to modern developments such as the varied and most important uses of whale oil, the increasing resort to mammal products in biological therapy, and the importance assumed by mammals as reservoirs of disease organisms of man or domestic stock, as in the case of cattle disease in Africa, or as the carriers and communicators of disease, as in the case of the vampire bat. This exhibition, and all such special exhibitions, will do much to keep alive general interest in museum collections, which are always in danger of becoming static and unenterprising.

Mounting Museum Specimens in Plastic

ONE of the great handicaps in making attractive to the ordinary museum visitor specimens of the smaller organisms has been the need for mounting such in formaldehyde, alcohol, or other fluid, which almost invariably bleaches colour and makes necessary awkward methods of attachment. To a considerable extent that difficulty has been overcome by the use of an acrylic resin, 'Plexiglass', the product of experiments conducted by Dr. Otto Rohm, of Philadelphia. Dr. Charles E. Sands, of the Bureau of Agricultural Chemistry and Engineering, has developed a method of embedding specimens in blocks of this material so that they resemble fossils preserved in amber, except that 'Plexiglass' is colourless and crystal-clear, clearer it is said than the finest glass, and will retain its transparency permanently. Specimens before embedding must be dehydrated in air or with alcohol or dioxan, and the setting is done in vacuum to prevent the inclusion of air-bubbles while the mountant is changing from semi-fluid to the solid state. A collection of miscellaneous specimens mounted in this way was on view at the New York World's Fair, and is permanently shown in the Franklin Institute in Philadelphia.

Fertility Rules in Fruit Planting

THE John Innes Horticultural Institution has produced a very useful leaflet (No. 4) with the above title, which sets out clearly the rules for interplanting fruit trees to ensure effective pollination. Based on many years of research to test the success of crosses between varieties of cherries, plums, pears and apples, this leaflet will be an invaluable guide to growers in the planning of new orchards and in the improvement in fertility of existing trees. It is estimated that the value of the total fruit crop of Great Britain could be increased 10–20 per cent by correct interplanting. In some existing orchards containing large blocks of trees of a single variety, much could be done to increase the crop by top-grafting a proportion of the trees with suitable pollinators. Brief reference is made in the leaflet to the causes of unfruitfulness, and exhaustive lists are provided to show which varieties are self-compatible and which varieties will ensure effective cross-pollination. Attention is directed to the reduced population of wild bees in many orchard districts and the necessity for keeping hive-bees in correctly interplanted orchards.

Feeding Value of Silage

FARMERS must be able to judge the feeding value of their silage, and to meet this need the Ministry of Agriculture has issued Bulletin No. 50 in the "Grow-more" series. High-quality silage is a cake substitute and can only be obtained from the right crop, cut at the right time and properly ensiled. The colour, smell, texture and dry-matter content of material in this category are described, and recommendations given as to the rate at which it should be fed. If any of the requisite conditions is not fulfilled, the silage can only be used to replace hay, roots, or oat straw. The value of such material varies considerably according to the type of crop from which it is made, or to the conditions during ensiling, but suggestions are given as to the rationing of several of the low-protein silages. For the less experienced farmer, a useful table is included, in which the common faults in silage, their cause and the appropriate remedy are described, and if still further information is desired, application can be made to the county agricultural organizer.

A New Pavlov Manuscript

MR. M. KRUTIKOV, who is working at the archives of the Academy of Sciences of the U.S.S.R., has discovered the manuscript of a hitherto unknown work by the Russian physiologist, the late Prof. I. P. Pavlov. The work, which had been submitted for a competition for a prize of the Academy, is entitled "The Centrifugal Nerves of the Heart", and it is dated 1885; it consists of 19 pages. It seems that when the manuscript reached the Academy it was handed for report to I. Tarkhanov, who, after some time, presented a long scientific review of the work. However, he failed to come to any definite conclusions about it, because of the absolute newness of the subject and the absence of any literature on it. It is hoped to include the new paper in the complete edition of Pavlov's works which the Academy proposes publishing.

The Linnean Society of London

General meetings of the Linnean Society of London are to be resumed at 3 p.m. on the following Thursdays: March 6, April 3, and May 1. On March 6, several papers will be read. The centenary of the Royal Botanic Gardens, Kew, as a Government institution occurs on April 1, and at the meeting on April 3, Sir Arthur W. Hill, director of the Royal Gardens, will give some account of the work of Kew during the past hundred years. At the meeting on May 1, the Society will keep the tercentenary of the birth of Nehemiah Grew, when Dr. Agnes Arber will give an account of him, and of Marcellus Malpighi. The anniversary meeting will be held on May 24, when the president will address the Society. The council is to consider the possibility of prolonging the session into June and July.

Announcements

Owing to the generosity of the Rockefeller Foundation, which has provided a grant for the purpose, the Royal Society is in a position to give some assistance to scientific societies and associations which, as a result of war conditions, are experiencing financial difficulties in the publication of scientific journals.

Among the bequests in the will of the late Sir Robert Hadfield, who died on September 30 last, are the following: gold and other medals, diplomas and certificates to the University of Sheffield for any library or museum in connexion with the Faculty of Metallurgy, and failing acceptance, to the Science Museum, South Kensington; his collection of alloy specimens forming the record of his various papers to scientific and technical societies to the Science Museum, South Kensington; £1,000 to the Imperial Cancer Research Fund; £1,000 to the Royal Society for general research work.

Dr. J. Burtt Davy, late University demonstrator in forestry in the University of Oxford, who died on August 20, bequeathed a bond for £7,000, secured on property in the Transvaal, or any of the capital paid, to the Chancellor, masters, and scholars of the University of Oxford, to found a scholarship, "The Burtt-Davy Research Scholarship", for research work in taxonomic botany and/or tropical plant ecology.

The University of Liverpool is to receive a sum of £2,500, under the will of Mrs. Mary Harmood Hamilton, to endow a scholarship or scholarships in the Faculty of Engineering.

Sir Andrew Davidson, county medical officer for the North Riding of Yorkshire, has been appointed to succeed Prof. J. Mackintosh as chief medical officer of the Scottish Department of Health.

Mr. Hector Leak has been appointed president of the Royal Statistical Society, to hold office until the next annual general meeting, in succession to the late Mr. Henry W. Macrosty (see p. 230 of this issue).

Mr. George Grant, registrar of University College, Southampton, since 1923, has been appointed registrar of the University of Birmingham to succeed the late Mr. D. J. Cameron. The status and stipend of registrar have been raised to equality with those of full-time professors.

The journal *Microentomology*, issued from the Natural History Museum of Stanford University (California), is now in its fifth volume. Among recent issues that have come to hand are contributions by Dr. G. F. Ferris and others on the detailed external morphology of selected types of the various orders of insects. These accounts are very clearly illustrated by well-executed figures that are intended to meet deficiencies in this respect in many existing publications. The journal, it may be added, is obtainable from the Director of the Museum, and individual parts are obtainable separately at a low price.

During the committee stage in the House of Commons of the War Damage Bill, Sir William Jowitt said, in reply to an amendment put forward by Mr. K. W. M. Pickthorn, one of the representatives of the University of Cambridge, that universities must be regarded, for the purpose of the Bill, as carrying on business. That being so, they would not be exempt from compulsory insurance, but he added that the Government would use its powers under the clause to exempt from the obligation to insure certain classes of the non-essential equipment of universities. He expressed the hope that the Government would receive assistance from the universities and their representatives in formulating a workable scheme.

A catalogue of books relating to Egypt recently issued by Mr. George Salby, oriental bookseller, of 65 Great Russell Street, London, W.C.1, has a special association interest for Egyptologists and students of the archæology of the Middle East. It includes the libraries of two well-known archæologists. First that of J. L. Starkey, excavator of Lachish, whose assassination by an Arab brought to a premature close one of the most illuminating of recent archæological excavations in Palestine; and secondly, that of Alan W. Shorter, assistant keeper of the Department of Egyptian and Assyrian Antiquities in the British Museum, whose early death cut short a career of much promise. In addition to books which might be termed the tools of a working archæologist, the catalogue includes a number of rarities, among them Prisse d'Avennes "L'Art Arabe", text with three volumes of 200 plates, Rosellini's "Monuments of Egypt and Nubia", and Arthur Upham Pope and Phyllis Ackerman's "A Survey of Persian Art from Prehistoric Times to the Present", the last-named a monumental and scholarly production.

Erratum. In the letter "Rheology of Plastic Materials" in Nature of February 8, p. 176, for the formula "$\psi = S\sigma^{4}t^{k}$" read "$\psi = S\sigma^{-1}t^{k}$".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Legal Protection of the Names of Animal Breeds

VERY often the name of a breed of animal, after being imported into another country, is changed there. This new name given by the importers leads to the impression that the breed is a new one and of native origin, for which the importer unfairly claims the credit, whilst it is really a foreign race. One must consider that this manner of appropriating the work of another is a fraud, and should be treated as such, just as literary plagiarists are punishable by law. Neither can the products of grading be regarded as a new race. It would be better to name the first generations of grades according to their different amounts of blood with regard to the polygenic characters, just as horse grades, for example, are called: $\frac{1}{2}$-, $\frac{3}{4}$-, $\frac{7}{8}$-, $\frac{15}{16}$-blood. As regards the following generations, closely resembling the pure breed of livestock, they should be given the name of the race used for grading, together with the name of the region where the rearing took place, as in the imaginary example: Southdown of Holstein. This name would describe a race of sheep bred in Holstein, being the result of grading native sheep with pure-bred Southdowns.

For the countries which export breeding stock it is of great economic importance to have the names of animal races protected legally. There are many cases known in which animals were imported to another country, multiplied and then advertised as new breeds and sold to another country again. Or in other cases crossbreds produced in some countries by crossing British or Swiss breeds with native stock were sold as pure-bred British or Swiss or under a changed name, as a new breed. These products, being crossbred, had no real breeding value.

This problem has a domestic importance in every country, and not only in connexion with the export of breeding stock. Some people lay claim to be creators of new breeds, simply by making single or double crosses of different existing breeds.

From the scientific point of view, it is also very important to know the origin of every breed, and the crosses used to develop a new type or breed. The use of genetical methods to improve animal breeding would be much easier if the origin of many breeds were not obscured, as is often done purposely.

In order to direct attention to this problem, which is so important to breeders and to the science of breeding, I read a paper at the Fourth International Congress on Animal Breeding in Zurich in July 1939, under the title "The Protection of the Denomination of Animal Races by Law". Afterwards I proposed to the Congress that it should pass a resolution to protect legally the names of animal races, a protection which would be of great value and importance not only from scientific, but also from economic and moral points of view. After a very lively discussion, the resolution was passed to put the matter in the hands of the "International Association for Animal Production" to be constituted. (See Proceedings of the Congress, Zurich, 1939, pp. 333 and 403.)

The subsequent breakdown in international relationships has arrested this promising start. It is in any case very desirable that a *controlling body should be established* in every country engaged in producing and exporting the breeding stock. The same body, it is proposed, should also have the power to decide when a new breed has been developed. The question of whether or not a group of animals could be called a new breed needs careful and individual consideration; every case should be judged on its merits.

The interests of Great Britain in this matter being so considerable, it seems especially needful to establish such a regulatory organization in this country, possibly with others in the Dominions. If other countries do establish similar controlling bodies, the question of linking them up and integrating them could usefully be gone into after the War as a preliminary to the resumption of international trade in breeding livestock. It would be fitting for Great Britain to take the lead.

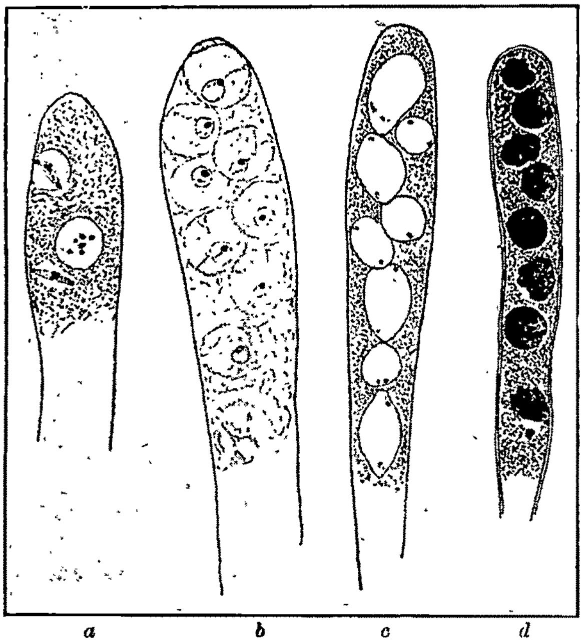
Ascospore Dimorphism of *Bulgaria inquinans*, Fr.

THE adult ascus of *Bulgaria inquinans* typically contains eight spores, four of which are large, dark and thick-walled, the rest being small, thin-walled and hyaline.

According to Moreau[1], the explanation of this dimorphism is to be found in the earlier development of the ascospores. He alleged that the three successive divisions of the definitive nucleus of the ascus were not synchronous, and this resulted in a precocious development of four of the ascospore nuclei. Then, during the subsequent differentiation, these nuclei became invested with a greater quantity of spore-plasm than the remainder, the final result being a spore dimorphism.

During an investigation of the cytology of this fungus, in the course of which two reduction divisions were observed in the earlier development of the ascus, a number of observations upon the development of



the ascospores was also made. None of these was in agreement with those of Moreau. No asynchronism of the mitoses in the ascus was observed, the number of nuclei present was always one, two, four or eight, indicating that the divisions were quite regular. The phases of the divisions were nearly always synchronous also, as is seen, for example, in the metaphases of the last meiosis, three of which are shown in the accompanying figure (*a*).

The mode of spore delimitation involving the participation of a nuclear beak and astral rays was quite normal, and at the time of the formation of the spore membranes the ascus contained eight isomorphic uninucleate spores. At this time also the ascospores passed from an ellipsoid to a spherical form (*b*). It is subsequent to this condition that the dimorphism begins. Four of the spores increase in volume and become ellipsoidal again, the others undergoing very little further increase. After the dimorphism has been established and the spores are assuming their final form, the nucleus of both types divides so that each is at least binucleate in the mature condition (*c*). The dimorphism here is thus dissimilar from that found occasionally in *Neurospora tetrasperma* (Colson[2]) and some other fungi, where the large spores are binucleate and the small uninucleate, since in the former the initial condition for all the spores is a uninucleate one, whereas in the latter the larger spores are initially binucleate.

An examination of asci in which the fatty material of the spores had been blackened by the osmic acid in the fixative showed that in young asci where there was as yet no external dimorphism, the arrangement of the osmicated droplets fell into two classes (*d*). They appeared in four young spores as flocculated and in the other four as consolidated masses, and an examination of even earlier stages showed that the latter was a condition derived from the former. The four spores containing the condensed fatty material increased in size and finally developed the thick brown walls characteristic of the large type. At the same time the osmicated substance increased in amount, finally breaking up into a small number of large droplets. No alteration from the original condition was observed in the small spores.

On account of the correlation between the above changes and the development of the dimorphism and the inability to support Moreau's conclusions, it is suggested that the cause of the condition is to be sought in a difference in the fat metabolism of the two spore types. In other words, the explanation is physiological rather than cytological.

A full account of this investigation will be published elsewhere.

Inhibition of Nitrification by Chromates

The occasional presence of chromates in sewages which receive discharges of trade effluents from the chromium-plating industry led us to investigate the influence of chromate on sewage purification processes. Samples of sewage containing sufficient potassium chromate to provide 1, 10 and 100 mgm. chromium per litre of sewage were treated in laboratory percolating filters, and comparisons were made with a control filter. The results, already published[1], showed the oxidation of organic matter proceeded satisfactorily with up to 10 mgm. chromium per litre, but that nitrification of ammonium compounds did not occur to the same extent as in the control filter.

In continuation of these experiments, the effect of chromates on the purification of sewage by activated sludge is now being studied. The activated sludge was built up by aerating domestic sewage until a sludge was produced capable of completely oxidizing 40–50 mgm. ammoniacal nitrogen per litre to nitrate within 12 hours at 18–19° C. When aerated with sewage containing potassium chromate equivalent to 10 mgm. chromium per litre, part of the activated sludge failed to produce nitrate within 24 hours, but instead nitrite was formed. Within 48 hours, following a second addition of sewage containing 10 mgm. chromium per litre, formation of nitrite and nitrate ceased: aeration with fresh additions of sewage without chromate failed to cause oxidation of ammonium compounds within a period of eight days. Other experiments with the nitrifying sludge showed that three charges of sewage containing 5 mgm. chromium per litre added on successive days was enough to arrest nitrification. The same phenomenon as before was observed, namely, that the sludge after contact with chromate did not recover its power of nitrification after aeration with sewage for one week.

The study of further aspects of this subject is now in progress, but it seems worth emphasizing that not only is the activity of organisms concerned with the production of nitrite and nitrate from ammonia arrested in presence of small concentrations of chromate, but also that the inhibitory action appears to last for a considerable period after removal of this inhibiting agent. Although nitrified effluents are not obtained by aeration with activated sludge in presence of chromate, it is still possible to obtain effluents which in every other respect are well oxidized and of high purity.

Origin and Nature of Heavy Ionization Particles Detected on Photographic Plates Exposed to Cosmic Rays

IN a previous communication[1] we gave an account of star-like tracks obtained in vertically placed Ilford Halftone plates exposed to cosmic rays at Sandakphu (3660 m.) and Darjeeling (2130 m.). We suggested that they were due to secondary mesotrons. Since then we have carried out a more detailed examination of these plates and also of other similar plates kept at Sandakphu for 202 days (i) under 20 cm. of water in a galvanized iron box, (ii) in a lead box with 5·5 cm. lead on the top of the vertically placed plates. The last-named plates on development were found to be fogged. Fortunately, the observations of Heitler and his co-workers[2] on similar plates exposed under different thicknesses of lead at Jungfraujoch supplement our observations and are in agreement with our results.

(I) In the course of our examination of the exposed photographic plates during the last year and a half, we observed a number of curved tracks on them. Our experience with proton tracks produced on similar plates led us to the view that the former could not be due to protons but were probably due to mesotrons. To test this point we exposed a Halftone plate to fast neutrons due to a radium-beryllium source, with 10 cm. of lead to cut off the gamma rays. Fast protons are produced in the material of the film due to collision of the fast neutrons with hydrogen atoms in the latter, and proton tracks up to 40 cm. air range were observed. The total range in air, the mean particle distance and the total angle of scattering of the cosmic ray and proton tracks are given in Table 1.

TABLE I

Track No.	Total air length	m.p.d.	No. of curved tracks	Sum of scattered angle
A. Sandakphu (air)				
1–22	380 cm.	5·5 μ	4	19°
23–45	356	4·2	9	57°
46–77	395	3·4	12	61°
78–87	107	2·7	2	12°
B. Proton tracks				
1–74	1111 cm.	2·6	2 single scattered 1 curved	

According to the theory of nuclear multiple scattering of charged particles, the mean deflection $\bar{\theta} = \frac{Z z e^2}{W} (Nt)^{1/2}$ (3·69+a log. correction term), where Z and z are the atomic numbers of the scattering and scattered particles, W the kinetic energy of the latter; that is, the scattering varies as $1/v^2$ of the particles. On the other hand, it is found empirically, and this result finds reasonable interpretations in the theory given by Helens and Wilkins[4], that the mean particle distance along the ionization tracks in photographic emulsion increases with the velocity of the particle, that is, the faster particle will be characterized by greater m.p.d. and smaller scattering. Judged according to this criterion the cosmic ray particles and the protons cannot be of the same kind, and assuming that they both carry the same charge, the former has a smaller mass than a proton. In view of the fact that we and also other investigators have failed to observe discrete tracks on photographic emulsions due to fast electrons, it can be reasonably concluded that the tracks recorded in Table 1 *A* are due to mesotrons.

(II) Absorption in water and air: In Table 2 is given the number of tracks observed in photographic plates kept at Sandakphu and Darjeeling under different conditions. To obtain a measure of the energy of the cosmic radiation, we have counted the number of tracks per cm.^{2} on the plates, excluding those tracks in which the mean particle distance is less than 2·2μ, as experience shows that such tracks are due to α-particle contamination.

TABLE II

Sandakphu	Plates kept under	No. of tracks per cm.^{2}/100 days	No. of tracks absorbed due to	Ratio of absorption
	(i) air	165	20 gm./cm.^{2} water	
	(ii) 20 cm. water	67	98	1·6
Darjeeling	(iii) air	103	140 gm./cm.^{2} air 61	

The conclusion can be drawn that the component of the cosmic ray responsible for producing heavy ionization tracks in photographic plates is more strongly absorbed in water than in air and that it is probably neutrons. The relative energy loss due only to elastic collision in the given masses of water and air of the high-energy neutrons responsible for multiple shower production, can be calculated from the following consideration. A neutron during such a collision with an atom of mass M loses on an average $2/M$ of its energy; that is, it requires $M/2$ collisions to produce the same loss of energy as collision with a hydrogen atom. We can then calculate the number of equivalent hydrogen collisions in the two media, and their ratio comes out 1·7, which is very near the observed value of 1·6.

The agreement between the two (if not accidental) can be made plausible on the following assumptions: (i) such high-energy neutrons are very seldom produced in the mass of air between Sandakphu and Darjeeling; (ii) the cross-section for elastic collision is large compared with that for shower production; and (iii) on an average they do not suffer more than one hydrogen-like collision.

According to the older perturbation theories of Bhabha and Heitler, the scattering cross-section of fast mesotrons by protons increases with the mesotron energy and is independent of the proton mass. The first of these conclusions and the order of magnitude of the scattering cross-section is not in agreement with experimental results. According to the revised theories proposed by the same authors[5,6], the calculated scattering cross-section is in agrement with the observed results, but the production of multiple mesotron showers is not possible according to it, while the older theory could account for it. Our results are thus not in agreement with the predictions of the newer theories. A recent theory of Heisenberg[7] appears to give a reasonable picture of multiple shower production by the impact of fast neutral particles on neutrons and protons; according to this view, the scattering cross-section of mesotrons diminishes with the increase of proton mass and has a much smaller value for high energies than that given by the older theory.

(III) We do not feel competent to judge the validity of the assumptions underlying the different theories; we have, however, tried to verify one consequence of the new theory proposed by Bhabha, according to which the following reaction is possible: $p+p \rightarrow p_2+n$. the minimum energy required is 35 Mev. and the cross-section for such a process is $3 \cdot 2 \times 10^{-26}$ cm.^{2}, which is expected to occur when a fast proton traverses about 45 cm. of water. We have examined the plate kept under 20 cm. water for 202 days for tracks of such double-charged protons. The latter will ionize like α-particles, and in order to distinguish them from the latter we have looked for such dense tracks of length greater than 10 cm. of air. In an area of $1 \cdot 05$ cm.^{2}, no such track was observed. The negative result may be due to the small number of high-energy protons present in the cosmic ray.

We are indebted to Dr. R. C. Mazumdar for directing our attention to Bhabha's paper.

Effective Frequencies of Sensitive Flames

Brown[1] showed in 1932 that if a graph of flame-height against frequency of the sound were plotted, there occurred a large number of maxima and minima, and that the frequencies of these maxima and minima were independent of the gas velocity, the shape and size of the jet, and the amplitude of the sound; and further, that those for hydrogen were indistinguishable from those for coal-gas. From his theory of edge-tones he has recently concluded that the reaction of the external air (the only constant factor) cannot be neglected[2]. In order to exclude the effects of resonance of all kinds, Brown repeated his experiments with entirely different apparatus in a different laboratory, but the frequencies remained unaltered.

Some recent observations of mine support Brown's results. They were made in the Department of Applied Physics in the University of Basle in Prof. Zickendraht's laboratory. The apparatus consisted of a Siemens-Halske oscillator, an amplifier and a 'Blue Spot' loud-speaker. Differently shaped brass jets were used, and the response to the sound was observed by measuring the change in the height of the coal-gas flame. The change in output of the oscillator-amplifier set was checked by a galvanometer placed in series with the moving coil of the loud-speaker, and care was taken to ensure that any maxima and minima of the output were eliminated by a sliding resistance.

It was found that the occurrence of the main maxima and minima of response depended only upon the frequency. The main minima were at frequencies of 1,200, 1,490 and 2,140, and the main maxima at 1,180, 1,470, 1,680 and 2,960. Comparison with Brown's detailed results shows good agreement. No marked maxima or minima occurred at higher frequencies with the jets used.

It seems, therefore, that, difficult as these results are to explain theoretically, they cannot be attributed to resonance either in the laboratory or in the apparatus.

Glaisher's Table of Powers

Is there any contemporary of Dr. J. W. L. Glaisher who can throw light even now on the mystery of his suppression of completed tables? The basis of the Table of Powers just published by the British Association [see p. 219 of this issue of Nature] is a table of the first twelve powers of the first thousand integers compiled by Glaisher. This table was finished in 1873 and was stereotyped, but it was not published. The plates were presumably destroyed, and the proofs seem to have been systematically hunted down. One copy survived in secret; Mr. H. J. Woodall found it among papers left by Lieut.-Colonel A. J. C. Cunningham, recognized its value, and presented it in 1935 to the British Association Tables Committee.

A similar story is attached to the Number-Divisor Tables prepared last year by the same Committee. Glaisher completed a set of tables for the Cambridge Philosophical Society in 1884, type was set up, plates made, and proofs pulled, and there the matter rested until ten years after Glaisher's death.

Also among Glaisher's papers were found volumes of manuscript tables of four theta functions, the denominator and the three numerators of the Jacobian elliptic functions, computed at degree intervals of the modular angle. This is an enormous piece of work, and apparently Glaisher was content that nobody should benefit from it. Why?

It is easy to account for the abandoning of an unfinished enterprise. The only obvious reason for the suppression of a finished table is the discovery of a systematic error, and Glaisher had not this reason. The British Association Committee submits all its material to the most drastic checks, and Glaisher's work was almost perfect: a missing digit in one table, a few accidental errors that his own process of checking would have detected in another, is the whole tale of faults.

In the preface to the Number-Divisor Tables, I wrote: "It is as if Glaisher knew too well the distance that separates accurate manuscript from faultless print, and could not force himself to the irrevocable step of authorizing publication". But this is sheer conjecture. Can no mathematical confidant, no reluctant printer, speak from knowledge?

ORIGIN OF METEORITES

IN the Halley Lecture* of 1940, Prof. F. A. Paneth presents a most stimulating and informative survey of the many hypotheses that have been proposed in the attempt to solve the difficult but fascinating problem of the origin of meteorites, with special reference to the evidence on which modern views are based.

In addition to the accepted groups of 'irons' and 'stones', Paneth follows Suess in claiming 'glasses' (tektites, etc.) as meteorites—despite the fact that no actual fall of tektites has been reliably observed—on the ground that, since hypotheses explaining the occurrence of tektites as products of human manufacture or as terrestrial formations can easily be disproved, there is no alternative but to assume that they are of celestial origin. Moreover, the hypothesis of Michel, adopted by Lacroix, that tektites are formed in the atmosphere by the oxidation of silicon and other elements, is disproved by the fact that the rapid flight through the atmosphere of these alleged elements would allow far too little time for reaction with the enormous volume of oxygen that would be required. Paneth throws out the suggestion that silica-rich granitic bodies representing the original material of the tektites may have entered the Roche limit of the sun and there suffered melting and dispersal, to form swarms of glass globules on cooling after leaving the perihelion neighbourhood. It has, of course, to be recognized that our interpretations of the origin of iron and stone meteorites may not apply to the glasses. In this connexion it is relevant that while there are transitional varieties between the first two classes, there is none whatever between either of them and the third. In what follows, therefore, reference is made only to iron and stone meteorites.

Evidence consistent with the origin of meteorites in the solar system is: (*a*) The close geochemical analogy between meteorites and terrestrial materials, even to the minor chemical elements and their distributions. (*b*) The identity in isotopic constitution of all the meteoritic elements so far tested with those of the corresponding terrestrial elements; this applies even to the radioactive elements uranium and potassium, and since the isotopic ratios of a radio-element vary with time, such identity points to the simultaneous origin of both meteoritic and terrestrial uranium and potassium. (*c*) Paneth's own determinations of the ages of iron meteorites, none of which is of a higher order than that now assigned to the earth: here it must be noticed, however, that with the coming into favour of the 'short' time-scale of the universe this item of evidence can no longer be claimed as an argument against an extra-solar origin for iron meteorites.

The chief astronomical arguments bearing on the birth-place of meteorites depend upon observations (*a*) of the orbits and velocities of falling meteorites; and (*b*) of the distribution of meteorite falls during the hours of the day. In a few cases heliocentric velocities have been recorded which are sufficiently high to imply an interstellar source for the meteorites concerned. Hoffmeister has, indeed, declared that the interstellar origin of a majority of meteorites is a "well established fact", and the preliminary results of Opik's researches at Arizona seem to support this claim. The evidence, however, is conflicting, and the validity of deductions from purely visual observations has been seriously questioned. Paneth refers to recent photographic studies by F. L. Whipple on nine sporadic meteors, which proved that at least eight, and perhaps all, were moving in elliptical orbits; he also cites the opinion of Fletcher Watson and C. C. Wylie that visual observations are inevitably subject to a systematic subjective error which always leads to the over-estimating of velocities. Clearly the interstellar hypothesis cannot be regarded as 'well established' and it is still more gravely weakened by the other line of astronomical evidence, which supports the alternative view that meteorites originated in the solar system. It is found that a majority of the meteorites seen to fall strike the earth between noon and midnight, and from this preponderance it can be inferred that most, and possibly all, meteorites move in 'direct' orbits. Niessl has argued against the validity of this inference, but Lindemann has in turn convincingly disposed of Niessl's objection. Summing up the whole position, Paneth thinks we may safely assume that meteorites have been members of the solar system since their formation.

Other points of interest discussed in the lecture refer to the conditions under which meteorites may have been formed and to their subsequent history. Recent attempts to reproduce the Widmanstätten structure show that it is not formed during solidification from a molten mass; but is due to a later re-orientation of the iron and nickel atoms which occurs while the crystals very slowly cool. The perfection of this structure in iron meteorites implies extremely slow cooling at a relatively high temperature. The parent mass or masses must therefore have had very considerable dimensions, an inference which is consistent with the common view that meteorites may be fragments of asteroids (or of a single asteroid) which came, perhaps several times, within the Roche limit of, say, Jupiter. C. C. Wylie has found that the Pultusk meteorites moved in elliptical orbits resembling those of the small asteroids in their eccentricities, inclinations to the ecliptic, periods of revolution, and mean distances from the sun. The widely varied 'ages' of iron meteorites further suggest that some of the asteroids or their fragments may have passed near enough to the sun to have had their earlier store of helium driven off.

The long and "rather wild" history of stone meteorites which can be read from their intricate structures also points to periodic heating and cooling, and this again suggests close approach, several times repeated, to the sun. Paneth does not overlook the tantalizing complications that this possibility introduces with regard to the development of the Widmanstätten structure. These and other points of detail—such as the origin of chondrules—continue to remain obscure.

Nevertheless, while admitting that the complete story still remains to be told, it is clear that the leading features of the origin of meteorites are now well within our grasp. Prof. Paneth is to be congratulated on a masterly review of a subject to which he himself has made notable and far-reaching contributions.

THE POPE COLLECTION OF ALCHEMICAL PAINTINGS AND ENGRAVINGS

By Prof. John Read, F.R.S.

THE late Sir William Jackson Pope, professor of chemistry in the University of Cambridge from 1908 until 1939, besides being one of the most eminent of British chemists, was known among the *cognoscenti* as a discerning collector of alchemical paintings and engravings. His treasures included many fine examples, either originals or engravings, of the work of the younger Teniers, Wijck, Bega, Steen, and other painters of the celebrated Dutch school of the seventeenth century. Among other items of much interest there was an unusually complete series of the rich reproductions in mezzo-tint of the paintings of Joseph Wright, the eighteenth-century painter of Derby, whose strangely effective high-lights are seen to such advantage in his representation of the discovery of phosphorus and in his charming study of a philosopher giving a lecture on the orrery.

There was also an impression of the rare engraving on copper, dated 1643, showing the experimenting Franciscan monk, Bertold Schwartz ("Black Bertold"), of Freiburg im Breisgau, "Doctor, Alchimist, und Erfinder der freijen Kunst des Büchsenschiessens, im Jar 1380", firing a charge of gunpowder with a flint and steel in his laboratory. Very exceptionally, the collection contained engravings in both 'enantiomorphous forms' of Teniers' "Le Plaisir des Fous": this famous picture, caricaturing the unintelligent operations of the 'puffers', or exoteric alchemists, depicts an ape seated at an alchemist's hearth with a pair of bellows, the operative paw being the right in one reproduction and the left in its 'mirror-image'. The pair of small engravings, which used to face each other upon the mantelpiece of Pope's study in Cambridge, naturally made a strong appeal to the great master of stereochemistry, who had taken delight for so long in the production of new and startling dextro- and lævo-forms in the laboratory.

One of the most attractive items in the collection was an original oil-painting, "The Chemyst", by Cornelis Pietersz Bega. This used to grace the entrance hall of the owner's Cambridge home, and it came from the Sawbridge-Earle-Drax Collection. Painted on a wooden panel, it is remarkable for the purity of its flesh-tones, its striking light effects, and its delicate tones of heliotrope and blue. An excellent black-and-white reproduction of this picturesque alchemical interior by Bega adorns the cover of a recent issue of *The Laboratory*, an interesting advertising periodical published in booklet form by the Fisher Scientific Company of Pittsburg, Pennsylvania.

Some time after the death, in October 1939, of Sir William Pope, his collection was acquired by the Fisher Scientific Company; having survived the perils of an adventurous passage across the Atlantic, it is now safely deposited at Pittsburg in the well-known Fisher Collection of notable pictures dealing with alchemy and historical chemistry. The Fisher Scientific Company has combined enterprise with good fortune in securing this handsome accession, and the pleasing thought is worthy of expression that the Pope Collection will preserve its identity in the new milieu.

It is a sign of the great interest taken by American chemists, both academic and industrial, in the historical evolution of their science that an American industrial corporation should take such pains in building up a purely historical collection of the kind under notice. While congratulating the United States most cordially on her clear vision and good fortune in this matter, all British chemists who appreciate the interest, inspiration and educative value of historical chemistry will entertain a feeling of regret that a collection of such outstanding merit as that of Pope could not have been preserved in Cambridge.

These beautiful alchemical paintings and engravings, together with the fascinating collections of drug jars and ornamented mortars brought together by the same hand, would have formed an artistic and unique addition to the Fitzwilliam Museum, besides providing a memorial truly characteristic of Sir William Pope, who accomplished more for the Cambridge school of chemistry than any other man.

EXCAVATIONS AT ELMSWELL, EAST YORKSHIRE, 1938

EXCAVATIONS on the Roman site at Elmswell, carried on by A. L. Congreve in 1936–37, were continued by Philip Corder in 1938 (*Hull Mus. Pub.*, No. 207; 1940). In the earlier investigations finds were both plentiful and remarkable, including thirty-seven coins ranging from one of the Iceni, coins of the whole Roman period and a barbarous type resembling a *sceatta*, pottery unstratified, but of the whole Roman period in the north, ending with an extensive collection of late fourth century ware, the earliest decorated Samian being of the period of Domitian, and stamped Saxon sherds; and a large pile of iron slag, estimated at half a ton in weight, "the product of direct reduction of fairly pure iron ore", which is similar chemically and petrographically to other Romano-British slag. The varied nature of the finds indicated a long period of occupation, which from other finds in the neighbourhood, evidently extended over an area of some square miles from the Bronze Age until Saxon times.

In 1938 a much wider area was trenched—in all about two acres. Ditches were traced, several areas of cobbling or roughly laid chalk blocks were uncovered and one hut floor was examined in detail. No stone-built house of Roman date—the principal objective—was discovered. Three more pits, similar to those already recorded, were excavated, and trenching on the triangular promontory some way from the main site revealed a solitary kiln.

The ditch proved to be shallow and not more than 8–9 ft. across. It must be interpreted as a boundary rather than a defence. Parallel to this, but 108 ft. to the east, was a second ditch, which must be considered part of the same system. All signs of occupation—

huts, floors and pits—lie to the north-east of this system. It is therefore improbable that an undiscovered Roman villa lies westward of the site.

In an otherwise undisturbed area south of the stream, a small kiln was discovered which, from the absence of a stoke-hole pit such as is found in a pottery kiln, is thought to have been an oven for roasting or drying wheat before storage. No part of the superstructure, if any, remains. Sherds found in or near the kiln need not be later than A.D. 120 or thereabouts, and two may be so early as the first century A.D.

Six pits have now been found. Two are double with a central ridge or division separating two hollows. All are relatively large, the largest being 17 ft. 3 in. in greatest length, and 9 ft. 4 in. in greatest width. Every one had been deliberately filled in by tipping in large quantities of wood-ash and dark soil containing charcoal and potsherds. Three were sealed or partially sealed by humps of clay burnt to brick-like hardness. These may have come from ovens or kilns. All are interpreted as storage pits, but two may possibly have been working hollows. The pottery from the pits is of mixed dating. The earliest indicate a date of first occupation late in the first century A.D., while the absence of Signal Station types show disuse before A.D. 370.

It is concluded that the site is that of an insignificant Iron Age village inhabited apparently without interruption from about the middle of the first century A.D. until at least A.D. 500. The chief occupation of the inhabitants was the production of corn. A kiln for the drying or parching of corn, working places where it was prepared for storage, pits for its preservation and an exceptionally large number of hand querns for its grinding are ample evidence for this. In addition, there are unmistakable signs of iron working. Lumps of iron slag on analysis and comparison with known Roman iron slags leave no doubt at all that it is a bloomery slag.

Evidence of regular habitation begins in the first century A.D. A fine piece of *repoussé* bronze work associated with *champlevé* enamel is to be placed in the third quarter of that century. From the pottery it would appear that the Parisii folk who lived here could afford to supplement their home-made pottery by acquiring Roman utensils almost as soon as these were available in the north after the conquest of the Brigantes and the permanent establishment of the Ninth Legion at York. From that time until the end of the fourth century there is no sign of a break in continuity of occupation as attested by coins or pottery. It is possible that occupation continued uninterrupted into pagan Saxon times. Sherds and small objects may date so late as A.D. 500. Hybrid types have suggested "Romano-British women making pots in the Saxon manner for Saxon masters". It is on such a site as this that one might find the enslavement of a sub-Roman population. Not deeply Romanized, they would change masters without serious dislocation in their way of life.

The panel of Celtic ornament from Elmswell, a remarkable example of Celtic art, which was found in 1938, is described by Philip Corder and discussed by C. F. C. Hawkes (*Hull Mus. Pub.*, No. 209; 1940). As it was unstratified and unassociated, its dating depends entirely on internal evidence. It consists of a thin sheet of bronze covered with an embossed design of flowing curves garnished with rosettes, and fitting on, along its upper edge, to an oblong cast-bronze strip decorated with champlevé enamel of a bright orange-red colour, in large part now discoloured green. Beneath comes an iron plate, now incomplete and corroded, which has been bent along its lower margin to form a flange. In all probability it is a panel which ornamented a wooden box or casket. Its dimensions are: length, 5 in.; breadth, 3·1 in. On technological, stylistic and historical grounds, it is assigned to British workmanship under Belgic-Romanizing influence. This conforms to the state of affairs in the Parisian territory of East Yorkshire in, and perhaps some little time after, the second quarter of the first century A.D. The different arguments concerning the style of the panel are summed up as pointing to a date A.D. 50–70, and most probably about A.D. 60 (see also NATURE, 146, 433; 1940).

FORTHCOMING EVENTS

Monday, February 24

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Surgeon-Commander Murray Levick: "The 1938 Expedition to Newfoundland" (Colour Films).

Wednesday, February 26

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Major C. P. Ackers: "Private Estates and Forestry".

Friday, February 28

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (in the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Mr. E. E. Bustard: "Preliminary Calculations in Ship Design".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SPEECH THERAPIST to the Yorkshire (West Riding) Education Committee—The Education Officer, County Hall, Wakefield (February 27).

PUBLIC ANALYST to the Soke of Peterborough County Council and the City of Peterborough—The Town Clerk, Town Hall, Peterborough (endorsed 'Public Analyst') (February 28).

PRINCIPAL of the Brighton Municipal Training College for Women—The Education Officer, 54 Old Steine, Brighton (February 28).

LECTURER IN DIETETICS AND ANATOMY—The Principal, Battersea Polytechnic, Battersea, London, S.W.11 (February 28).

ASSISTANT MASTER (GRADUATE) to take GENERAL ENGINEERING SUBJECTS including ENGINEERING DRAWING AND APPLIED MATHEMATICS—The Principal, Twickenham Technical College, Egerton Road, Twickenham (March 1).

ASSISTANT DIRECTOR at the Anglo-Uruguayan Institute in Montevideo—The British Council, 3 Hanover Street, London, W.1 (endorsed 'Uruguay') (March 1).

GRADUATE (MALE) for the English Room, University of Oporto, Portugal—The British Council, 3 Hanover Street, London, W.1 (endorsed 'Portugal') (March 1).

DEPUTY ENGINEER to the Essex Rivers Catchment Board—The Clerk to the Essex Rivers Catchment Board, Essex Rivers House, Springfield Road, Chelmsford (March 3).

HEADMASTER of the Sunderland Junior Technical School—The Director of Education, Education Offices, 15 John Street, Sunderland (March 10).

LECTURER FOR ENGINEERING DRAWING AND OTHER MECHANICAL ENGINEERING SUBJECTS—The Secretary, Northampton Polytechnic, St. John Street, London, E.C.1.

LECTURER (MAN OR WOMAN) in the Department of Pure and Applied Science—The Registrar, Loughborough College, Loughborough.

THREE ASSISTANT CONSERVATORS OF FORESTS—The Controller, Sudan Government London Office, Oxford Hotel, 261 Clifton Drive South, St. Annes-on-Sea, Lancs. (endorsed 'Conservator of Forests').

A BASIS OF INTERNATIONAL CO-OPERATION

IN preparing for the new world order to be established after the War, we must clearly draw whatever conclusions we can from the experience of the last twenty years, seeking to embody the lessons we learnt in the constructive effort of framing a new peace settlement. The truth that nothing short of an economic revolution can give us security has been emphasized by many authorities of widely differing outlook, but the extent to which a foundation already exists for further constructive and creative effort is often overlooked. Notably is this true of the work of the International Labour Organization and of the non-political work of the League of Nations.

The last report of the director of the International Labour Office visualized the important contribution which the organization might make to human welfare even with the outbreak of war, and that forecast has in no way been invalidated with the removal of the Office to Montreal in view of the increasing difficulties of communication between Geneva and member States. From the quarters placed at its disposal by McGill University, as well as from the correspondence offices in London, Washington and Delhi, the organization is continuing its activities, albeit on a reduced scale, as well as assisting in surveying social and industrial changes brought about by the War. Not the least valuable of these activities are the admirable series of publications, including the *International Labour Review*, the *Industrial Safety Survey*, the "I.L.O. Yearbook", and "Yearbook of Labour Statistics", as well as further studies and reports, the issue of which is now to be resumed from the new home at Montreal.

The practical value of the work of the International Labour Organization in preparing peace, emphasized by the Secretary of Labour at Washington in November 1939, has indeed been accentuated as the struggle has intensified, and one country after another has been drawn into the War. The support afforded to the policy adopted by the governing body gives eloquent proof that the organization has an essential part to play at this critical juncture in the fortunes of civilization. That function is essentially a contribution to the preservation of the common heritage of civilization.

"The future of humanity depends upon the type of civilization which emerges from this war, the kind of world institutions which are constructed after it, and the intensity of the allegiance which they command, upon the common man, upon the nature of its impact upon political ideals and upon economic and social practice, upon the manner in which it affects the crisis in social evolution which dominates our time." Nothing which has occurred has invalidated this estimate by the Director of the Office in October 1939, and the existence of this agency for disinterested technical assistance, the concerting of practical measures to limit moral and national havoc within or without the war zone, and to maintain co-operation between Governments, employers and workers represents an immense advance on the forces available for reconstruction available in 1918.

If, indeed, the International Labour Organization represents in some measure that scientific detachment without which we may well be unable to achieve some of the essential reconstruction and rehabilitation, in the non-political achievements of the League of Nations itself there are equally sound reasons for hoping for an advance on the position of twenty-five years ago. To the value of these achievements an admirable article in the American quarterly *Foreign Affairs* by Mr. Arthur Sweetser, a director of the League secretariat, testifies. The League's own reverses, notably in the Disarmament and Economic Conferences and in the Manchurian and Ethiopian disputes, have distracted attention from its solid but less conspicuous successes. This distortion of our understanding of events since 1919 may conceal valuable clues as to the planning and rebuilding which lie ahead of us.

Mr. Sweetser rightly points out that any political institution is a reflection of the society from which it has sprung, and the League of Nations, in particular, has been a vivid expression of the period into which it was born. Its record is valuable both as an index of the stage which international life has at present attained, and as an augury of the course we may expect it to take in the future. The sharp interruption of the varied work of international co-operation carried out at Geneva for two decades, involving the cessation of conferences, drastic reduction of staff, and transfer of some of the technical services, commencing with the financial and economic, to the United States on the joint invitation of the three educational institutions at Princeton—the University, the Institute for Advanced Study, and the Rockefeller Institute for Medical Research—provides indeed a most appropriate opportunity for appraisal of these non-political achievements.

The value of such stocktaking is indisputable, for it is on the assets that remain that the new organization of international co-operation will be built. The need for such co-operation will tend to increase, not only because the ravages of war must be repaired, but also through the relentless advance of science, the continual widening search of industry for specialized materials and the growth of the world's population. Only international organization of the world's life can prevent another and even more calamitous disaster.

The impetus which the League has given to international co-operation is unmistakable. The provision by the League system of a permanent Civil Service supplied with funds and authority, and able to collect and preserve records and statistics, and to enlist and to use the services of experts from all countries, is one of the main reasons for the advances made in the last two decades in handling a wide range of technical questions, from financial and economic problems to the control of opium and other drugs and the consideration on an international scale of health, including nutrition.

Without going into the details of the League's remarkable achievements in these technical fields while international friction was reducing its effective political power to a mere shadow, they present several features which merit attention. A noteworthy part of the financial section and economic intelligence service is the provision of an admirable series of publications which give the world for the first time something of a detached scientific view of the problems covered by the section, in place of the partial or national point of view from which such matters have in general hitherto been approached. The development of this scientific approach and the introduction of something of the scientific spirit into the examination of all these technical matters well justifies General Smuts's observations in his Sidgwick Memorial Lecture. If this is indeed one reason for the success of the League in such technical fields, it may well hold a clue as to the correct approach in other fields also.

A second feature to which Mr. Sweetser directs attention is the unexpected quarters from which the stimulus leading to important advances often comes. The League's first effort in the field of nutrition was made in Japan, where an inquiry was held by the League at the request of the Japanese Government. In this work Australia has taken a leading part, notably through her delegate to the League Assembly, Mr. S. M. Bruce. Moreover, the committee set up under his chairmanship, and known as the Bruce Committee, has already pointed the way forward to social and economic developments of the utmost importance.

Important contributions have by no means been limited to the States members of the League. The success of the League's work in the field of opium and international health has been largely due to the co-operation of the United States. Throughout the last two decades the tendency has been for such co-operation in technical matters to increase, independently of the way in which the political situation might encourage or discourage American co-operation with the League in strictly political affairs. Experience does, indeed, suggest that the United States will be ready, after the War, to take a share in the economic reconstruction on which the hope of the recovery of Europe depends, and that there are no inherent obstacles in the League's organization to the constructive technical and economic work which must proceed side by side with, if not as a prelude to, political reconstruction.

Another significant feature in the technical work of the League which is noted by Mr. Sweetser deserves special attention. Delegates at Geneva handling such problems are often far ahead of their Governments at home. As perhaps might be expected, not only have they a strong sense of the urgency of the problems they are discussing, but also they tend to approach them from the professional point of view, with its desire for constructive and appropriate action. This urge to obtain an adequate technical solution to such problems is reinforced by the larger perspective in which the problems are viewed, and the corporate spirit inspired by the day-to-day process of give and take.

In contrast to this, ministers and officials at home are still in a national atmosphere, subject to all sorts of inhibitions and jealousies. The narrowing of this gap, between what a diplomatist viewing the world as a whole recommends and what a local politician at home is willing and able to accept, is indeed one of the great problems facing the future.

Much is involved in any such efforts at extending the cool, serious, and detached spirit of science into national and international government. The impartial examination of the facts is only the preliminary stage, and perhaps the most elementary contribution which professional organizations, whether of scientific workers or other types of experts, have to make to social advance. A wide vision, minds imaginatively alive to the human issues involved, cool in judgment, and willing, if need be, to sacrifice position or career rather than be false to the truth as they know it, or the vision they have seen—these are first among the qualities which will build us a new and better order. The measure in which they have been revealed in many ranks of society under the searching ordeal through which we are still passing is alike a sure pledge of victory and an earnest that we shall not fail to reap its fruits for all mankind.

BIOLOGY FOR THE MILLION

The Uniqueness of Man
By Dr. Julian Huxley. Pp. xiii+300. (London : Chatto and Windus, 1941.) 10*s.* 6*d.* net.

"THE UNIQUENESS OF MAN" is a book full of good reading, very diversified and occasionally very provocative, like the mind of its author. Julian Huxley is, among other things, the natural successor to Ray Lankester, the ripe and abundant author of "Science from an Easy Chair". These papers vary in quality from the admirable essay which gives the book its title to a cheery little review of "Who's Who", which lines up with its betters as "The Analysis of Fame". Such papers as "Climate and Human History", "The Origin of Species", "The Concept of Race", and "Mice and Men", are exactly what the man of intelligence, mainly preoccupied with other work, needs to keep him up to date with his biological ideas. The concluding three papers are 'religious' and very earnest in tone.

The title paper, written for the *Yale Review*, is done with a carefulness and precision not always evident in Dr. Huxley's fluent writing. It gives an extremely good survey of the profound gulf that has opened between *Homo sapiens* and the rest of the animal kingdom out of which he has arisen in the brief space of at most a quarter of a million years, a mere moment in geological time. This gulf was cleft open by conceptual thought. Already before then the anthropoid apes were an odd outstanding group of animals descending gingerly from the trees; but although their hands were comparatively free, Dr. Huxley tells us, they had no means of transmitting and handing on ideas. Then came words. With conceptual thought man established a mental and moral continuity and a power of assimilating social groups, additional to and far more effective than the links of consanguinity and physical inheritance He developed a novelty in the history of life, "cumulative tradition", and so by means of the word he escaped from the limitations of the small churlish family group hitherto characteristic of other anthropoids. That may not be wholly true. There may have been an intervening phase before the spoken word dominated us, when man had already achieved a certain power over general ideas by means of gesture. Many peoples can still converse by gestures with words as accessories. Man may have begun with gesture and mimicry, with grunts and sounds arising out of his movements. He may have been visual in his communications before he became vocal. He may have drawn and made tally marks long before he used common nouns or numerals in counting.

It is perhaps an impertinence for a general reader to criticize the precision of a distinguished man of science; but occasionally there is a very perceptible laxity and tolerance in Dr. Huxley's phrasing and mental attitude that is not in the best scientific tradition. He says that man has acquired the possibility of a unified mental life. The work of Pavlov and the Behaviourists goes all out to sustain the idea that he is only now acquiring it; and then, lapsing from a psycho-synthetic to a psycho-analytic phraseology, Dr. Huxley speaks of "the forces of disruption". He cannot have it both ways.

Again he seems to me too ready to deal with telepathy and clairvoyance as something new and extraordinary in human experience. But has he really worried out the possibility that the mind may work at times with a swiftness that eludes observation? A friend of mine is a crossword puzzle addict. He tells me that occasionally he can take *The Times* crossword puzzle and write down the solution with scarcely a hitch. At other times he sticks, and, sometimes, even after a considerable effort, he sticks hopelessly. Now *The Times* puzzles are very whimsical and various in their clues, and guessing them means that my friend must run over a very great store of memories, associations, possibilities and alternatives, and put this and that together. There can be no telepathy by means of the printed page. His clairvoyance, I suggest, is just extremely swift clear-mindedness. He flashes to his end and the intermediate steps vanish. The rapid answers of a calculating boy probably fall into the same category of swift reactions with no record of the steps. There is no 'extra-sensory gift' in such cases, but only indications of an enormous range in the pace of our mental processes. The same individual in different phases will vary between what we call intuition and blank impenetrability. Observations on the reactions of a fly to stimuli and of the quick decisions of a frightened cat escaping from some unfamiliar enclosure confirm the idea that ganglionic and brain responses may be immensely accelerated in comparison with everyday humdrum human experience. I am still unconvinced that there is anything quasi-occult in these apparent triumphs of the human mind over the theory of probability.

Let me now hurl a final reproach at the author for his curiously unscientific indisposition to pin himself down to unambiguous statements. His concluding papers on religion are rational and right-minded. I have no quarrel with their general trend. But this is how he winds up:

> "I believe that we can never reduce our principles to any few simple terms. Existence is always too various and too complicated. We must supplement principles with faith. And the only faith that is both concrete and comprehensive is in life, its abundance and progress. My final belief is in life."

Here we are supposed to cheer and disperse in a mood of edification. I refuse to do so. What does this belief in life mean? We are alive. How can we avoid believing in life? What is the alternative? Is this an assertion that, to put it vulgarly, "life is O.K. for me"? How can one accept that nowadays? I can understand the stoic's stern pride in the life within himself. I can understand the scientific worker's devotion to truth—truth with the utmost possible precision at any cost—for how can one be a man of science without that? I can understand the man whose head is "bloody but unbowed" under the bludgeonings of chance. Maybe Dr. Huxley will reply that he agrees with all that? Then why cannot he bring himself to say so quite distinctly?

H. G. WELLS.

BIRDS OF LUNDY

Lundy: Isle of Puffins

By Richard Perry. Pp. 268+24 plates. (London: Lindsay Drummond, Ltd., 1940.) 12*s.* 6*d.*

FOR five months during the spring and summer of 1939, Richard Perry lived on the island of Lundy, an Atlantic island off the coast of Devon, in order to study the birds. Day after day, and even into the deepening dusk, he watched and observed them, and in this book are gathered together his notes.

Never, perhaps, have sea birds been studied so minutely during the whole of their nesting season, and Mr. Perry shows that he possesses to an unusual degree the gift of keen and accurate observation. The sea birds most fully described are the puffin, kittiwake, razorbill, guillemot, and cormorant. There are interesting chapters on the birds of passage and on the island's history. The book is illustrated by thirty-seven photographs by Alan Richardson, and some of them—for example, those of the kittiwakes—are remarkably beautiful.

The author was able to watch the epic journeys of the young of razorbill and guillemot to the sea from their nesting ledges. I quote a graphic passage (p. 139) on a young razorbill's first flight :

> "Shortly after nine o'clock [on the evening of July 17] one mystery was solved when an old razorbill came down from the top of the gully some two hundred feet up, accompanied by a big chick which made a perfect flight down, its diminutive wing stumps whirring as swiftly as a bee's, its little paddles spread wide in the appropriate manner. A 'scarl' of excitement from other razorbills lining the route extolled its triumph."

This young razorbill was accompanied by one of its parents. But what of a youngster who makes this first flight unattended ? The tragedy which then follows is vividly portrayed on pp. 143–144 :

> "At a quarter past nine [at night] a chick suddenly appeared from nowhere in the water at the bottom of the gully and swam directly out to the open sea, crying its continual 'psee-ee-ee, psee-ee-ee', with wide-open bill. For some minutes it plied around outside the entrance to the gully, often looking up at the cliffs ; but no parent came to meet it. Its fate was inevitable, for it was still quite light, with a fine sunset reddening the North Cape. I waited sadly. Down came the accursed gull, as deadly quick as ever. And though the little fellow dived, and though three guillemots, waiting on their own chicks flighting down, made an onslaught on the gull, the latter hooked him by one shank and carried him dangling to a nearby reef. Then the monster beat and tore the life out of him savagely, though he struggled valiantly and with astonishing tenacity."

That the author can write well and vividly may be realized from his description of kittiwakes (p. 92):

> "It is during the intervals of comparative quiet that a marvellous thing happens, when, suddenly, hundreds of kittiwakes zoom down from the ledges at a single impulse, shoaling out of the gully in a dazzling white and grey pack that has an hypnotic effect on the eye. Like snowflakes in a blue heaven, they wheel mazily over the whirlpools of white surf and the deep green Atlantic swell. By what miracle of flight-control do they avoid collision ? One will sometimes drop its brown webs and buffet another with its furled wings. And then with one accord the hundreds wheel around and soar up to their ledges in the gully. Their tumultuous clangour when they alight is almost overwhelming."

Take, again, his description (p. 59) of the first landing of the puffins on Lundy in March :

> "While I sat for hours half hidden, an unbroken column of red-billed, red-webbed puffins hurtled with menacing directness at my boulder, swaying from side to side on the gale : like streams of tracer bullets radiating to their respective boulders seventy yards up and down the Slope. Sheering off easily, without shock, from my head, with a soft flutter-thud of keeling wings, the short black leaf-points of their spread tails projected fanwise on either side of their scarlet or orange shanks, as they turned to plane down to the sea with great *élan*.
>
> "Hovering delicately, with flickering wings and hanging rose paddles, some pitch neatly on to their boulders, bowed forward into the wind, like turnstones, with great bills uptilted and convex wings lifted for some seconds well above the level of their backs in the manner of an alighting beetle, before standing fair and square on their vermilion shanks, so brilliant against the dull green and yellow lichen of the grey rock. But they soon take off again, drooping at head and stern, with perfect swallow-dives, and quiver like black hawk moths down the Slope : red webs, clasped together, stretched out behind, delicately fluttering wings arched a little convexly—a most graceful, fragile motion. They circle swiftly out over the sea, often mounting to four or five hundred feet with quick-beating whirring wings, and rejoin the throng of their fellows flighting like a scattered swarm of starlings hawking winged-ants."

There is a fine description, too, of the departure of the young guillemots from their ledges (p. 178 *et seq.*).

When the author can write so well, it is something of a shock to come across his lapses of style. For example, on p. 95 an account of the doings of kittiwakes brings the dreadful opening of a sentence, "As per usual", which shatters the flow of vivid narrative. The author, too, is fond of long and strange words : "exteroceptively" (p. 212) ; "territoried" (p. 184) ; "pre-incubationary" (p. 121) are examples. What is a "black-sitting" egg (p. 125) ? Nor is his habit of naming the greater black-backed gull the "great gull" or the "big gull" one to be commended.

It is of considerable interest to realize that the Lundy shags build their nests and lay so late in the season. Mr. Perry found that the first nest-building in 1939 took place on April 28, and the first egg (by the way, he is wrong in describing the shag's egg as "glossy") was not laid until May 24 (p. 218). In the north of Skye, a full 400 miles north of Lundy, I expect to find shags brooding their eggs by the first week in April, and have seen nesting material brought as early as February.

In his chapter, "Home from the Sea", the author advances an interesting theory to account for the periodic return, from mid-winter onward, of sea birds to their nesting rock. That ocean bird, the fulmar, I myself have seen at its breeding rock in early January, when the ground was hard frozen, and icicles hung from the cliff edges.

It is refreshing that the War should have failed to stop the publication of this book, which must be a source of interest, and of pleasure, to all bird lovers. SETON GORDON.

SCIENCE, NATIONAL AND INTERNATIONAL, AND THE BASIS OF CO-OPERATION*

BY PROF. A. V. HILL, O.B.E., F.R.S., M.P.

ONE of the great tasks lying before scientific people after the present War will be to rebuild, and to rebuild on a firmer and better foundation, the international scientific organizations which have come into being in the last seventy years, particularly during the present century. The earliest of these was the International Bureau of Weights and Measures, established in 1873. An International Geodetic Association followed, and in 1903 an International Seismological Association on the same lines. Arising from the initiative in 1898 of the Academies of Munich and Vienna, together with the Royal Societies of Göttingen and Leipzig, which had all been in the habit of meeting annually, the Royal Society of London undertook to approach a number of foreign academies with a view to the formation of an international association of academies. As an independent institution, not subject to State control as were so many of the academies, the Royal Society was in a very favourable position for opening such negotiations. As a result the International Association of Academies was formed, which held five meetings in all, the sixth at St. Petersburg being cancelled owing to the outbreak of war in 1914. It never met again.

These meetings were not limited to natural science, many of the academies being concerned both with the scientific and the humanistic side of learning. It is interesting to interpolate that as one result of this movement, and in order to represent Great Britain on the literary, philosophical and historical sides, the British Academy was formed and incorporated by Royal Charter in 1902.

Just before the end of the last war, in 1918, representatives of the academies of all the allied countries met in London, and later in Paris, to discuss the formation of a new international scientific organization. In July 1919, the first General Assembly of the International Research Council, as it was to be called, met in Brussels. Representatives of the Central Powers were not invited, and a misunderstanding which then arose was made an excuse for declining an invitation which was sent to each of them a few years later. This unfortunate state of affairs persisted. German professors who feel themselves insulted are difficult people to appease, and indeed the fault was not all on their side. International Unions for Astronomy, Geodesy and Geophysics, Chemistry and Mathematics (this last no longer in existence) were formed; and at the next General Assembly in 1922, for Physics, Scientific Radio, Geography and Biology. Some of these Unions have functioned well and have held important international congresses and done important work; others have done little. The ones that have worked best, for example, Scientific Radio, are those which had a more practical international task to fulfil.

These Unions always had an official or semi-official flavour: official delegates, official hospitality, official finance, official business, have tended to put independent science into a somewhat subordinate position. Physiologists have held international congresses for fifty years, and great value these have had, as we who have taken part in them know: but physiologists have always insisted that they came as independent men of science, to meet, to hear and to discuss things with their colleagues; not as representatives of some State institution or interest. Other scientific groups have held similar informal congresses based on the same idea. There is grave danger, as was found by the Physiological Congress meeting in Italy in 1932, and in the Soviet Union in 1935, of a congress being used as an opportunity for political propaganda; in 1938 this was altogether avoided by the tact and understanding of Swiss colleagues, as it had been avoided at meetings prior to 1932. Political considerations are hard enough to avoid anyhow, but they are much worse if a congress is not genuinely independent.

In Great Britain and in the United States, the strength and the high position of the independent scientific societies make it easy for them to take charge of the proceedings of a congress, or of an inquiry of international importance, without danger of State control—either in appearance or reality. But this is not so easy—indeed it has been impossible in recent years—in many countries. In order to preserve the integrity of science in our own country, it is very important that those strong independent scientific bodies should be maintained; and for the sake of international scientific relations it is desirable that in other countries also, so far as we can influence them, the domination of the State over science should be tempered by public appreciation of the part played by independent scientific agencies and institutions.

In some form or other, not one may hope

---

* From an address given at the annual general meeting of the Parliamentary and Scientific Committee on January 28.

exactly in their present form, these international unions must be started up again some day. This time, at any rate, we shall not be prevented from following our better judgment by the intransigence of French colleagues; though it may be hard enough for us this time to take a detached view. My own feeling is that in this matter we should rely, so far as possible, upon the help and advice of our American scientific friends. Their views about science, for its own sake and in relation to the State, are much the same as ours, and they (at present at least) are further from the battle. I know they would regard it as a sacred trust of friendship to bear a large part of the burden of starting off again the international co-operation in scientific endeavour which was so unhappily ended by the events of the last years. There is a high idealism in the United States about international co-operation in the field of science and learning, and a very great regard for British science and British scientific men. If the War goes ultimately as we expect, in the downfall of dictatorship and tyranny, it will be our job to start off again, on broader and better lines, the complex system of international scientific co-operation; and in starting it off I am sure that we shall be able to call for the help and co-operation, without stint or limit, of our scientific friends in the United States.

I have spoken several times of the necessity of guarding the independence, the spiritual integrity of science. In many countries to-day science is wholly subservient to the State; its soul is not its own. I do not deny for a moment the importance, indeed the necessity, of scientific organizations within the framework of Government, or of liberal support by the State of scientific research. One can only welcome such recognition by the public of the importance of scientific knowledge and scientific discovery—and ask for more. There are several things, however, which one may fear. First, the condition of stagnation and complacency which tends to develop in any scientific department or establishment which is cut off from outside criticism or ideas; we have far too many examples of this already, and if we are not careful they will multiply. Secondly, the danger that science will be planned by administrators in offices instead of by young men with their sleeves rolled up in laboratories or workshops. Thirdly, the disadvantage of separating teaching from research, to the great loss of the next generation, who may miss the inspiration of seeing discovery going on in the places where they are taught. Fourthly, a decrease in the influence and prestige of those independent scientific bodies which play so large a part in the social and intellectual activities of the scientific community and provide the cross-connexions between groups which might otherwise be isolated. Fifthly, the danger that he who pays the piper may call the tune, and that research may be required to be devoted primarily to objects which the politician, or the Civil Servant, regard for the moment as of national importance; or even—as in Germany and the Soviet Union—to bolstering up theories which the official philosophy of the State prescribes.

To avoid all these troubles, the independence and integrity of science must be carefully preserved; in the universities, in the learned societies, in the various associations or institutions devoted to the advancement of knowledge. Whenever State support is given, a buffer should be interposed, similar to that provided by the University Grants Committee between the universities of Great Britain and the Treasury. In our existing Research Councils (Department of Scientific and Industrial Research, Medical Research Council, and Agricultural Research Council), working with Government funds, the buffer is already provided by the fact that the members of the Councils are chiefly independent scientific men. The same safeguard exists at present with much of our State-aided research; we must carefully watch that the strength of this safeguard is fully maintained, that it does not become a formality, and that the principle is consciously extended wherever possible, as the financial burden of scientific research and development is taken over (as is bound to happen more and more) by the State.

In many of the departments of Government, however, notably those of the defence services, scientific research is undertaken, on a grand scale, which cannot be controlled directly by outside independent bodies. In these establishments particularly, the danger of stagnation and complacency exists. They are devoted to specific service purposes, often of necessity secret; and the condition of secrecy prevents them, in ordinary times, from attracting many of the ablest and brightest minds, who prefer the freer atmosphere of the universities, the possibility of discussing and publishing their results, and the recognition of their colleagues resulting therefrom. Consequently, in war, those who direct these establishments are often men who have arrived at their positions by seniority and long service, during which they have been largely isolated from the ideas and criticism of current scientific thought; it has been difficult for them not to become officials rather than working men of science. When an emergency occurs, as at present, numbers of able men come in, but to posts in which they can exert relatively little influence, and their ability and imagination may for long be imperfectly used. This indeed is inevitable under the present system, for they have at first no experience of service conditions and needs. After a year or two perhaps—longer than necessary—these able people find their proper level, but not until much damage has been done by lack of imagination and energy in the posts they might have filled before.

To avoid this trouble—and it is a very real one—two main principles may be applied. First, to introduce into each department or organization some kind of scientific advisory council, similar to that which on the whole works so well now in the Ministry of Supply. This council should consist partly of independent scientific men chosen for their special knowledge on one hand, for their wide contact with the scientific community on the other; and partly of official scientific people representing not only the department or organization itself, but also a variety of other departments, so that a good cross-section of official knowledge and experience is available. Secondly, in ordinary times to arrange for regular interchange of personnel between the Government research establishments and organizations, and the universities and other independent institutions in which research is carried on.

I know that this second proposal will shock some of those who have lived in the traditional secrecy of service science; but it is right all the same. Why should not a chemist or mathematician from Woolwich, a physicist from the Signal School, an engineer from the Royal Aircraft Establishment, go back as a lecturer or professor to a university, or to the research staff in a commercial laboratory; just as a physiologist from the National Institute for Medical Research, or an aeronautical engineer at the National Physical Laboratory, or a zoologist at the Marine Biological Laboratory at Plymouth, may do? And why should not the research workers in Government laboratories be just as regular attendants at the meetings of scientific societies as those in other institutions?

The first need is for a common pension scheme. All scientific workers, whether in the universities, or in commercial laboratories, or in Government employment, should come under the Federated Superannuation System for Universities, as do those employed by the Department of Scientific and Industrial Research, the Medical Research Council and the Agricultural Council. Then the Departments should insist on sending their people away at intervals, to carry on research elsewhere and to refresh their souls in institutions outside. Conversely, they should invite outside scientific workers (naturally under proper safeguards of secrecy when necessary) to work for corresponding periods in their establishments. The advantage of this second step would be that the importance and interest of the problems which are being tackled in Government establishments would be more commonly realized, and better men would be inclined to take part in their solution. In the defence services a reserve of officers and other ranks is an essential part of an efficient organization for war; in the scientific services similarly, a reserve of research workers, for the case of emergency of any kind, would seem to be equally essential.

One great advantage of working in the scientific establishments either of the Government or of a large company or corporation, is the fact that equipment is not limited below the minimum that is necessary for efficiency. As regards research in the universities of Great Britain, I should feel inclined, if a Government fund of say one million pounds were available for scientific research, to ask the University Grants Committee to allocate it to different universities. Each university would then deal with the disposal of the sum allotted to it, in much the same way as the Royal Society does with the Government Grant for Scientific Investigation; and as in the last few years the University of London has already done with a substantial fund which it has put aside for this very purpose from its own resources. I know from long experience, both personally and by helping to administer the Royal Society grant, the great advantage to the individual and to the institution where he works, of the possibility of obtaining a grant, possibly large, more often small, for a specific research project; to be expended by the young research worker (or the older one) at his discretion and not merely by the department. What the University of London has made a start in doing in this way, can be done by other bodies; but money will be required. In the days of straitened circumstances which we cannot but foresee ahead, it must come from the State if scientific investigation is to be kept up—as it must be; and the natural body to allocate it to its different claimants among the universities would be the University Grants Committee.

For research in industry, in medicine and in agriculture (apart from their overlap with university institutions) the machinery for similar grants exists already in the three Research Councils; with extended financial provision from the Treasury if necessary. In industry, at least part of the sum required should be subscribed by the industry itself, as it is at present, with the research associations devoted to various subjects and working in co-operation with the Department of Scientific and Industrial Research. The personal grants given at present by the latter Department for researches "of particular timeliness and promise" are of great value and could with advantage be extended.

THE FAUNA OF NEW ZEALAND

By H. Barraclough Fell

NEW ZEALAND has provided biological science with the classical and most striking case of the effects upon a fauna of prolonged isolation. For an immense period of time it has remained a sanctuary for archaic types. The facts about the kiwis, ground-parrots, wekas and other flightless birds are quoted in perhaps every zoological course in the universities of the world. Yet, these very animals so important to science are now in the gravest danger of becoming extinct[1] like the giant eagles and moas before them. The aid of zoologists in Britain and elsewhere is urgently needed to support the efforts being made by New Zealand workers to bring about reforms to save these animals, which, once lost, will never be known again. It is insufficient to have passed laws purporting to 'protect' them, when inadequate wild-life administration is available to enforce the laws. Active measures must be taken as soon as possible to destroy the complex of introduced pests which have ousted, or actually attacked, the defenceless native species. The problem is of the utmost importance, and we owe it to future generations, and especially to future biologists, not only in New Zealand but also throughout the rest of the world, to solve it now.

Last year New Zealand celebrated the first centenary of organized settlement. The time is opportune, therefore, for a general survey by qualified workers to ascertain the present position of the native animals and plants after one hundred years of contact with European forms. Such a survey would be in the interests of biologists everywhere, and its commencement should be urged by overseas societies. There is in existence already, in the Forest and Bird Protection Society of New Zealand, an organization capable and willing to undertake the work if sufficient support were forthcoming. The survey, if undertaken, would aim not only at establishing clearly the detrimental factors which have operated upon native forms during the period of settlement, but would also be concerned with finding effective remedies for the ills which are now besetting this unique fauna and flora, and with urging the adoption of the remedial measures by the Government. Despite the efforts of New Zealand biologists (notably the late Dr. Leonard Cockayne, the late Mr. H. Guthrie-Smith, and the Forest and Bird Protection Society), apathy has prevailed so long that it seems that only pressure from overseas can bring the country as a whole to realize the gravity of the position. Collaboration between New Zealand biologists and others (especially those working throughout the British Commonwealth) to decide a policy to be pursued, with concrete suggestions for a method of approach based on the facts ascertained from a wide and thorough survey, will do more to convince the New Zealand Government of the urgency of the matter than anything else.

The present position was expressed by Dr. C. G. Morice and Mr. B. C. Aston in April of last year, when they wrote: "Much has been said, but nothing done so far, in setting on foot a scheme to bring about improvement in the administration of wild-life matters. Opposition has, on the other hand, come from those bodies who receive revenue from licenses for the killing of fish and game. Thus we have the same old story, that an attempt is being made to sacrifice the interests of the majority of sportsmen on the altar of personal interest. In the meantime this Society continues to receive a large number of reports indicating ruthless poaching, illegal collecting, and other breaches of the existing Act, and, we fear, must expect to continue to receive such, in the absence of an adequate warden service. The waste of funds expended on guesswork decisions continues as in the past, and points more than ever to the need for adequate research by trained observers in the field."[2]

The value of national parks has been urged constantly by the Society,[3] and gradually such parks are being set up. The famous Tongariro National Park, in the North Island, took its origin in a gift to the nation from the Maori chief Te Heuheu. It has since been increased in area by the efforts of the Royal Society of New Zealand. As the introduced vermin, however, are still at large, much of the value of these areas remains incapable of realization. For example, in the Mount Cook National Park the flora is still being ravaged by the chamois and thar introduced for tourist publicity purposes, while the effect of weasels on the fauna of the same area has been described by A. P. Harper[4]. The back-country mountain ranges have, to some extent, acted as conservation areas by virtue of their difficult access. It has been proposed to celebrate the centenary by opening up a scenic highway in the Tararua Ranges, near Wellington. Realizing the danger to the native fauna and flora from fire and interference, the Forest and Bird Protection Society has made an effort to oppose the plan[5], which as yet, apparently, has not been put into operation. Kāpiti Island is an example of successful conservation on a small scale, but unfortunately is exceptional.

Some actual facts may be quoted to illustrate the tragic spoliation which is at present taking place. In 1925 the Forest and Bird Protection Society urged upon the Government the need for reservation of the Auckland Islands on account of their remarkable sub-antarctic bird fauna, particularly the nesting grounds of the albatross. The Government of the day refused on the grounds that the annual rental of the islands as a sheep station (£40) was of greater value than the avifauna. In 1934, after the sheep project had proved a costly failure, the Government officially reserved the islands. The sheep, however, are still there, and the destruction goes on[6,7].

It has been estimated that there are a million cats in New Zealand, many of them having gone wild; probably some ten million birds are destroyed every year by these animals alone[8,9]. A cat belonging to a lighthouse keeper has destroyed an entire species (the endemic Stephen's Island flightless wren)[10]. Weasels and stoats rob the nests of the flightless wekas—birds which serve as protectors of other native species owing to their destruction of rats[11]. As the weka declines in numbers, so the rats are increasing, and the native birds grow fewer and fewer. Every year many kiwis and wekas fall victims to the traps of the opossum-hunters[1,12]. Wild pigs, dogs, and human interference have combined to make kiwis scarce in all but the remotest areas.

The evils of badly conducted acclimatization are notorious in the case of the rabbit. Not so well known overseas are some of the other examples which are having an equally disastrous effect upon the native fauna. The unfortunate introduction of the German owl by the Otago Acclimatization Society has burdened the country with a voracious pest which does not hesitate to attack and kill fantails, warblers, tomtits and other small native birds[13,14]. The native owl, or morepork, awaits darkness before beginning to hunt, and thus does not attack native birds. The introduced Australian black swan supplants the less vigorous native duck and teal by taking their food. Shooting by sportsmen has also reduced their numbers, and in this particular matter the present Minister of Internal Affairs has repeatedly warned the acclimatization societies of the need for conservation[15]. The draining of the swamps deprives the pukeko of its natural haunts, and drives it into the open, where it is shot by thoughtless sportsmen. The warnings of naturalists on this matter[16] have gone unheeded.

Man himself has committed great evils against the native fauna, and still is doing so. Reischek and his fellow commercial collectors of the last century filled the museums of Europe with the dried or stuffed skins of New Zealand's rarest birds. Their native country, alas, knows the living species no more. Thus was lost the huia (*Heteralocha acutirostris*), a bird unique in having radically different skull-forms in the two sexes. Mistakes such as these will not be repeated. But in the matter of commoner species, destruction is still going on, and other species may yet be extinguished by man. Thus, every year all species of shags are shot by fishermen on the supposition that they eat trout. The Forest and Bird Protection Society has shown that only one species, the black shag, is responsible; but the shooting goes on[2]. Godwits are shot every year during migration when they gather at the North Cape before making their six thousand mile flight to Siberia[17].

In an attempt to replace the forests which had for too long been allowed to be depleted, thousands of acres of quick-growing *Pinus radiata* and other exotic conifers were planted. No native plants grow on the darkened, needle-covered floors of these artificial forests; there is no native bird-life where there are no natural berries for them to eat[18,19]. The Nothofagus forests on many of the ranges are now dying or already dead owing to the introduced deer stripping the bark from the trees with their antlers, and destroying the absorbent mosses of the sub-alpine forest floor[20,21]. In the train of this destruction has come erosion, and in this matter the Government has been forced to act[22,23].

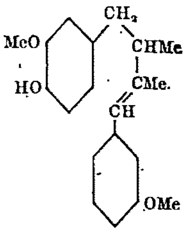
CONSTITUENTS OF NATURAL PHENOLIC RESINS

By Prof. R. D. Haworth,

University of Sheffield

THE resinous secretions and deposits of plants are frequently resolvable into crystalline carboxylic acids, alcohols and phenols of terpenoid or *n*-propylbenzenoid (C_6–C_3) structures. Abietic acid and the amyrins are examples of terpenoid constituents, and cinnamic acid and coniferyl alcohol represent C_6–C_3 types. The widespread occurrence of the C_6–C_3 structure in plant pigments, essential oils, amino-acids, alkaloids, resins, etc., is of special interest in connexion with the natural phenolic resins, from which a group of compounds possessing the skeleton structure,  $C_6\text{–}C\text{–}\underset{\underset{\displaystyle C}{|}}{C}\text{–}\underset{\underset{\displaystyle C}{|}}{C}\text{–}C\text{–}C_6$, has been isolated. These substances occur in many natural orders of plants, but their frequent association with the heartwoods and exuded resins of the Coniferæ is noteworthy. The term 'lignan' was introduced[1] to include all substances containing this carbon framework, derived from the combination of two C_6–C_3 units at the β-carbon atom of the C_3 chain. The lignans are catechol derivatives differing in the degree and kind of alkylation of the phenolic groups and in the state of oxidation of the non-aromatic portion of the molecule. The structural formulæ and natural sources of the lignans are included in the accompanying formulæ, where a convenient classification into three sub-groups, *a*, *b*, and *c*, is adopted.

(*a*) Diarylbutanes

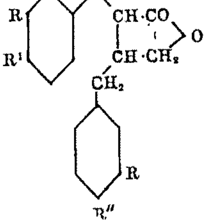


(I)

Lignans:

l-Guaiaretic acid
l-Dihydroguaiaretic acid $(\text{–}\underset{|}{\text{CH}}\text{–CH}_2\text{–}$ for $\text{–}\overset{|}{\text{C}} = \text{CH–})$

Occurrence: *Guaiacum officinale* (wood)

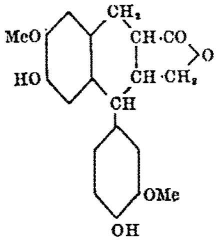


(II)

Lignans:
l-Matairesinol (R = OMe ; R′ = R″ = OH)
l-Hinokinin (RR′ = RR″ = CH_2O_2)
l-Arctigenin (R = R″ = OMe ; R′ = OH)
l-Cubebin (RR′ = RR″ = CH_2O_2 ; with CHOH instead of CO)

Occurrence:
Podocarpus spicatus (wood)
Cupressus obtusa (wood)
Arctium lappa (seeds)
Piper cubeba (seeds)

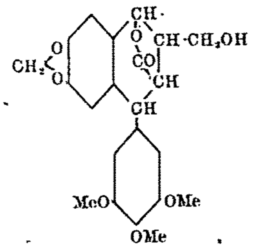
(*b*) Tetrahydronaphthalenes



(III)

Lignan: *l*-Conidendrin

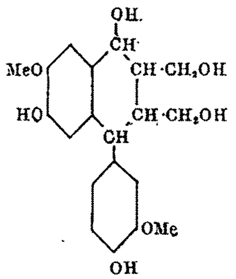
Occurrence:
Waste sulphite liquors
Tsuga Sieboldii (wood)
Picea excelsa (wood)
Podocarpus spicatus (wood)



(IV)

Lignan: *l*-Podophyllotoxin

Occurrence: *Podophyllum peltatum* (roots)



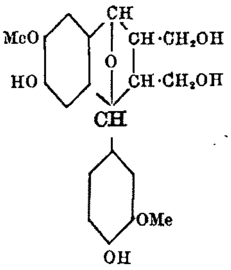
(V)

Lignan: *d-iso*Olivil

Occurrence: *Olea Cunninghamii* (wood)

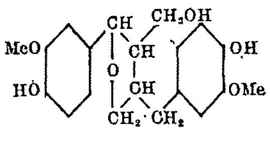
The ethers of the three sub-groups, *a*, *b*, and *c*, are attacked by nitric acid in different ways; the diarylbutanes give dinitrolignans, the tetrahydronaphthalenes yield amorphous products of unknown constitution, and the tetrahydrofurans are degraded to 4:5-dinitroveratrole[2]. Reduction at the benzyl ether linkages is characteristic of the tetrahydrofurans, and the dimethyl ether of *d*-pinoresinol (VIII) may be reduced either partially to the dimethyl ether of *d*-lariciresinol (VII) or completely to the *l*-diol (IX; R = CH_2OH)[3]. The diarylbutanes and tetrahydronaphthalenes are also distinguishable by oxidation of the lignan ethers; the former are degraded to substituted benzoic acids, and the latter yield a substituted *o*-benzoylbenzoic acid and a dibasic acid of type (X; R = CO_2H)[4]. Furthermore, smooth dehydrogenation of tetrahydronaphthalenes can be effected with lead tetra-acetate[5], and the conversion of the methyl ether of *l*-conidendrin (III) into the lactone (XI) orientates the lactonic group of conidendrin and excludes an alternative based on structure (XII).

(c) TETRAHYDROFURANS



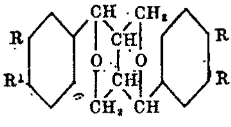
(VI)

Lignan: *l*-Olivil
Occurrence: *Olea europea* (resin)



(VII)

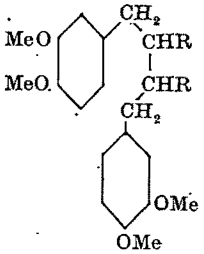
Lignan: *d*-Lariciresinol
Occurrence: *Larix decidua* (resin)



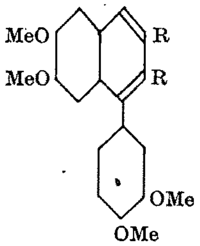
(VIII)

Lignans:
d-Pinoresinol (R = OMe; R′ = R″ = OH)
l-Eudesmin (*l*-pinoresinol) dimethyl ether (R = R′ = R″ = OMe)
d-Forsythigenol *epi**pinoresinol) monomethyl ether (R = R′ = OMe; R″ = OH)
d-Sesamin (RR′ = RR″ = CH_2O_2)
l-Sesamin
l-Asarinin *epi**sesamin)
Occurrence:
Pinus nigra, Pinus silvestris and *Picea abies* (resin)
Eucalyptus hemiphloia (kino)
Forsythia koreana (leaves)
Philyrea latifolia (bark)
Sesamum indicum (seeds)
Asarum Sieboldi
Asarum Sieboldi, Asarum Blumei Duch.

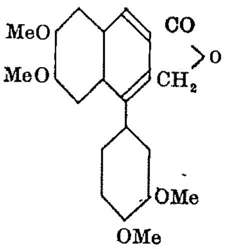
* *epi*Pinoresinol and pinoresinol differ in the stereochemical configuration at one or both of the α-carbon atoms.



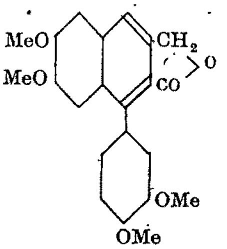
(IX)



(X)



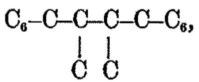
(XI)



(XII)

The dimethyl ethers of *l*-guaiaretic acid (I), *l*-olivil (VI), *d*-*iso*olivil (V) and *d*-lariciresinol (VII) are converted into the substituted naphthalenes (X; R = Me), and the dimethyl ether of *d*-pinoresinol (VIII) into the furan (XIII), on heating with selenium[6]. This reaction is not applicable to methylenedioxy lignans; but these may be related to the corresponding methoxy derivatives by demethylenation and subsequent methylation.

Derivatives of types (X), (XI), (XII), and (XIII) retain all the carbon atoms of the lignans, but lack the optical activity associated with the natural products. Methods for the synthesis of compounds of types (X; R = CO_2H or Me)[5,7] (XI)[8], (XII)[9,10], (XIII)[6] and (XIV; a degradation product of *d*-lariciresinol)[11] have been developed, and the inactive lignan derivatives have been identified by comparison with synthetic specimens. The establishment of the structures of these lignan derivatives provides a proof of the presence of the fundamental carbon framework,

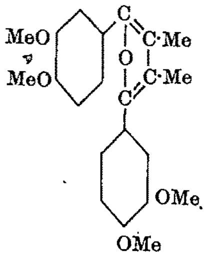


$$C_6{-}C{-}\underset{\substack{|\\ C}}{C}{-}\underset{\substack{|\\ C}}{C}{-}C{-}C_6,$$

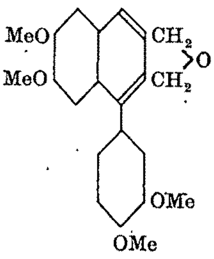
which applies rigidly to all products represented by formulæ I–VIII. A synthesis of the optically active modifications of type (II) has also been introduced and applied to the synthesis of *l*-matai-resinol and *l*-hinokinin[12]; but complete syntheses of other optically active types are not available. Numerous partial syntheses have, however, been realized by interconversion of members of the lignan group, for example:

$$\begin{tikzcd}
l\text{-cubebin} \arrow[r, "(13)"] & l\text{-hinokinin} \arrow[r, "(14)"] & l\text{-matairesinol} \arrow[r, "(15)"] & l\text{-conidendrin} \\
 & & d\text{-pinoresinol} \arrow[r, "(3)"] & d\text{-lariciresinol} \arrow[u, "(16)"']
\end{tikzcd}$$

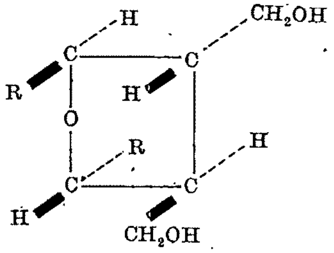
The lignans present an interesting stereochemical problem in which some advance has been made. Natural lignans of type (II) are synthesized from optically active anyhdrides of dibasic acids of type (IX ; R = CO_2H)[12], and unless optical inversion occurs during the reaction, a *trans* configuration must be assigned to the product. The hydroxy-acid obtained from *l*-matairesinol is partly converted by hot alkali into a diastereosomeric modification, and comparison[10] of the rates of lactonization of the two hydroxy-acids supports the *trans* configuration of *l*-matairesinol. The presence of asymmetric centres at one or both of the α-carbon atoms is an additional complication in the tetrahydronaphthalene and furan subgroups, but there is considerable evidence that the matairesinol configuration of the β-carbon atoms is retained throughout the lignan family. The conversion of the methyl ethers of *d*-pinoresinol and *d*-lariciresinol into the *l*- (and not *meso*-) form of the diol (IX ; R = CH_2OH)[3] supports this view.



(XIII)



(XIV)



(XV)

The proof that the phenolic groups are symmetrically disposed in *l*-olivil[17] and *d*-pinoresinol[18], together with the optical activity, shows that these molecules, whilst lacking planes, centres and alternating axes of symmetry, must possess a symmetry axis. Numerous configurations are eliminated by these requirements, and the remaining structures (two for each lignan) retain the matairesinol configuration at the β-carbon atoms. Little information is available concerning the configuration at α-carbon atoms. Cinnamic acid and coniferyl derivatives occur naturally in the stable *trans* form, and Vanzetti[19], postulating that lignans arise from the union of two coniferyl molecules, has proposed the *trans* structure (XV ; R = guaiacyl) for *l*-olivil. A comparison of the properties of the four modifications of 1-phenyltetrahydronaphthalene - 2 : 3-dicarboxylic acid[20] suggests that the most stable acid possesses *trans* linkages in the 1 : 2- and 2 : 3-positions, and this conclusion inferred from a compound containing three asymmetric centres is consistent, so far as it goes, with the *l*-olivil structure (XV).

Although the synthesis of lignans from C_6–C_3 types has not been reported, the widespread occurrence of the unit and the formal analogy of the coniferyl-lignan to the terpene-diterpene relationship indicate the importance of the C_6–C_3 unit in the construction of natural products. Tri-coniferyls, corresponding to the triterpenes, are unknown ; but the few established structural features of lignin chemistry are consistent with the view that lignin represents the polyterpene of the C_6–C_3 metabolism. The absence (or small proportion) of phenolic groups in lignin suggests, however, an important difference in the mechanisms of the hypothetical polymerizations of the C_6–C_3 type to lignans and lignin respectively.

OBITUARIES

Prof. Miles Walker, F.R.S.

DR. MILES WALKER, emeritus professor of electrical engineering in the University of Manchester, whose virile personality, sometimes tempestuous, always lovable, endeared him to all, passed peacefully away on January 22, at the age of seventy-three. Prof. Walker had by no means relinquished the strenuous life in favour of a country retirement, so well earned and so open to acceptance in the delightful home he had chosen amongst the Cotswolds at Amberley. The tale of Walker's career sounds strange unless one realizes the intense persistence which was so marked a characteristic in him.

Trained originally for the law, and in fact fully qualified and in practice in a solicitor's office in London, Walker found the lure of physics and engineering irresistible; this urge had been kindled and then thwarted when, as a boy, he browsed in his father's library in such books as Fownes "Chemistry", and visited his engineer uncle at Naworth Collieries, only afterwards to be articled to solicitors in Carlisle. Jumping the traces then in 1891, he registered as a student under Sylvanus Thompson and John Perry at Finsbury Technical College, London, being considerably older than his fellow students, and indeed continuing to pursue his law practice for a time.

To Walker the lectures proved fascinating, and he was delighted to find himself actually handling the tools, instruments, and machines he had read about. There was then no turning back for him. It is doubtful whether Walker had any preconceived career in mind when, in 1896, after acting as personal research and literary assistant to Sylvanus Thompson for three years, he proceeded to Cambridge to read for the Natural Sciences Tripos and afterwards the Mechanical Science Tripos, gaining a first in each (1898–99). It happened just then that the British Westinghouse Co. was inquiring from Prof. J. A. Ewing for engineering students whom it could send for a while to the works of the Westinghouse Electric and Manufacturing Co. at East Pittsburgh in the United States, to form upon their return a technical nucleus at the newly established Trafford Park Works. Walker joined that party of some forty and proved to be an outstanding member.

Walker's work at Trafford Park, as designer of alternating current machinery during the period 1903–12, refused to be trammelled by accepted traditions of design, and such innovations as the multiple radial commutator for high-speed D.C. generators, the locally saturated cylindrical rotor of self-regulating turbo-alternators, and novel features in rotary convertors and phase advancers came forth prolifically. But how could Walker but kick against the traces in a commercial organization with its necessary restrictions! Keen as he ever was for the practical, he found his real niche upon accepting in 1912 the chair of electrical engineering at the School of Technology, Manchester, that is, under the Faculty of Technology of the Victoria University, but retaining touch with practice by acting as consultant to his old firm—afterwards named Metropolitan-Vickers Electrical Co. Ltd.

Many examples could be given of Walker's persistence and nursing of a problem for years; for example, the identity of mathematical relationship subsisting between fundamental quantities in gravitational and electromagnetic problems had often caused him to question whether there might not be a gravitational effect corresponding to mutual induction. He had pondered on this at least as early as 1899, and the advice of authorities in Cambridge at that time had not definitely discouraged experimental work, but his first opportunity to investigate occurred after taking up professorial work in 1912, when he started a research student upon the problem. Using a 480-lb. vertical spindle flywheel as inducing mass, close to but elaborately shielded from a 23-lb. porcelain disk as receiver carried by a bifilar suspension from the top of the building, Walker was able to determine (Walker and Stainer, *Phil. Mag.*, **32**, 592–600) that if any such mutual inductive effect existed, the ratio of change of moment of momentum induced to that inducing it, must be less than 5×10^{-10}, a result reached only after a succession of precautionary measures.

It was typical of Walker that, pleased as he was with the final determination of this minute upper limit, his concern for his research student became pronounced lest the negative nature of the result should detract in fact from the assessed value of the investigation in the matter of academic award to the student.

During the War period, 1914–18, Walker was an active member of the Lancashire Anti-Submarine Committee, but he also devoted much attention to other war problems of his own devising. In 1924, when Sir Ernest Rutherford at the Cavendish Laboratory needed to produce very large momentary magnetizing forces, he turned naturally to his friend Walker, asking him to advise Dr. Kapitza. Walker was able to make valuable suggestions in the matter and to arrange for the work to be suitably placed. This plant later formed part of the equipment of the Mond Laboratory at Cambridge.

Throughout his life, Walker was an idealist impelled by very strong convictions and conclusions, arrived at, he believed, with unanswerable logic. He was in consequence sometimes difficult in debate although always transparently honest and sincere. These ideas were often unconventional and ranged over the whole spectrum of human welfare; thus his address as president in 1932 of Section G to the British Association started on an engineering basis but was soon frankly given over to a humanistic review, and even so had been much expurgated by Walker, regretfully, but upon previous official advice. Walker was an ardent supporter of the M.K.S. system of units, of rationalized spelling of English, and of universally available cheap electric supply.

Walker married in 1903 Miss Eveline Sargent, and they later adopted two boys in whose education and up-bringing they jointly found much pleasure. The boys are now serving in the fighting forces. Walker married in 1935 Miss Valeria D. Ellis, who survives him.

Walker was an untiring author, having served a notable apprenticeship during his association with Sylvanus Thompson. His best-known books are: "The Specification and Design of Dynamo-electric Machinery", "The Diagnosis of Troubles in Dynamo-electric Machinery", "The Control of Speed and Power Factor of Induction Motors", "Conjugate Functions for Engineers". He served as special lecturer at the Imperial College of Science and Technology in 1911, and at the Massachusetts Institute of Technology in 1921. A. B. Field.

Sir John McFadyean

We record with regret the death of Sir John McFadyean, formerly principal of the Royal Veterinary College, who died on February 1 at the age of eighty-seven.

John McFadyean was born on June 17, 1853, the second son of Andrew McFadyean of Barrachan, Wigtownshire. He received his early education at the Ewart Institute and later proceeded to the Royal (Dick) Veterinary College, Edinburgh, from which he was admitted to membership of the Royal College of Veterinary Surgeons in 1876. On obtaining his diploma he was appointed lecturer in anatomy at the College and while so engaged attended classes at the University of Edinburgh as a medical student, graduated bachelor of medicine and master of surgery in 1882 and bachelor of science in the following year. In addition to his teaching in anatomy, McFadyean turned his mind to pathology and bacteriology, subjects then in their infancy. In 1892 the curriculum of veterinary education was extended from three to four years, and far-reaching changes were made in the general standard of education. McFadyean, who had already made a name for himself by his work on tuberculosis, was appointed professor of pathology at the Royal Veterinary College, London, and two years later became principal, which office he held until 1927.

There are few diseases of the domesticated animals to which he has not contributed valuable information, and numerous select committees and Royal Commissions have been largely guided and assisted by his knowledge and experience. He was a tireless worker, and for many years his private researches were carried out during the night hours. In 1888 he founded the *Journal of Comparative Pathology and Therapeutics*, in which much of his work is recorded.

McFadyean was a great principal and a great man of science; but he will be best remembered by a grateful profession as an equally great teacher, for he possessed eht rare gift of imparting his knowledge to his students in a manner which was readily understandable. By his work he showed nearly half a century ago that there were new and wider fields of veterinary science to be explored. His researches into diseases affecting animals in tropical and sub-tropical countries as well as in Great Britain and in Europe, created what has now come to be known as preventive veterinary medicine and by his teaching he provided the pioneer workers in this new field. We owe it to his sound knowledge and foresight that the veterinary profession was prepared to move in this direction far in advance of official demands.

In 1893 McFadyean was elected a member of Council of the Royal College of Veterinary Surgeons, and was president of that body from 1906 until 1909 and again during 1930–31 on the occasion of the meeting of the International Veterinary Congress in London, "McFadyean's Congress" as it was called by the eminent foreign delegates who attended from all parts of the world. During the forty-seven years that he served on the Council, McFadyean's personality dominated its deliberations, as it did the field of veterinary science, and the profession owes much of its solid progress through that difficult period to his wide knowledge of men and matters. On his retirement from the principalship of the Royal Veterinary College in 1927 he was elected an honorary associate of the Royal College of Veterinary Surgeons, the highest honour that that body could bestow, and in 1933 he received the first award of the diploma of fellowship *honoris causa*. After his retirement Sir John pursued his studies with unabated enthusiasm, absorbed almost until the end in his great life-work for veterinary science.

In 1883 he married Mara Eleanor, eldest daughter of Thomas Walley, principal of the Royal (Dick) Veterinary College, Edinburgh. She died in 1929. He leaves three sons and two daughters, to whom we offer our sympathy in their bereavement.

J. B. Buxton.

Mr. C. Thurstan Holland

On November 5, 1897, less than a year after the discovery of X-rays, a paper on the subject was read by Sylvanus Thompson at a meeting which was held to inaugurate the formation of the Roentgen Society. Among those present at this meeting were a few medical men who decided to devote themselves to the application of the new discovery to the needs of medicine. Of this very small band Thurstan Holland was one, and within a few years he had become the most eminent exponent of this new branch of medicine in Great Britain. He was elected president of the Roentgen Society in 1904 and again in 1916. In his address on the latter occasion he wrote: "It is twenty years since I took my first radiograph, twenty years brimful of interest, and of advances which in those days none of us could have even dreamed about, advances which may perhaps be illustrated by the fact that the first successful radiograph I saw taken [by Oliver Lodge in January 1896] was that of a hand, and the exposure was

1¾ hours". He lived to see such exposures made as a routine in 1/10 second, even with apparatus that was mobile and could be readily taken round the wards to the patients.

In the rapid evolution of medical radiology and its applications to almost every branch of medicine and surgery, particularly in urinary radiology, Thurstan Holland took a leading part. He was one of the first to demonstrate the presence of a stone in the kidney and to obtain the shadow of the kidney outline as a *sine qua non* of a satisfactory radiograph of the kidney region. His meticulously careful technique and expert knowledge of photography resulted in the production of radiographs that were far in advance of standard practice for many years. Moreover, he brought to the task of the interpretation of his results exceptional clinical experience that was coupled with logical and rapid judgment. Little wonder, therefore, that he made his mark not only as a pioneer but also as a leader.

Although he practised in Liverpool, he nevertheless found time to keep in close touch with his colleagues in London, where he served on almost every radiological committee of importance. His commanding presence and outstanding personality were asociated with an exceptional rapidity of judgment and a knack of getting down to essentials· His influence on committees was profound.

Thurstan Holland's contributions to the literature of medical radiology were numerous and covered a wide field. So early as 1898–99 he wrote on the successful treatment of lupus and eczema by means of X-rays. Later he turned his attention to the diagnosis of chest conditions and those of the urinary tract. Working with his friend the late Sir Robert Jones, he made many valuable contributions to the study of diseases and abnormalities of bones. The Royal College of Surgeons acknowledged the value of this work by electing him as a fellow of the College. A list of about a hundred of his papers up to 1922 lies before me, covering practically every field of medical radiology that had been explored up to that time.

During the War of 1914–18 Holland served as a Major in the First Western General Hospital. His common-sense methods in the localization of foreign bodies were adopted by many radiologists.

He attained to all the honours that were possible in his branch of medicine and was president of the Electro-therapeutic Section of the Royal Society of Medicine, of the Roentgen Society (twice), of the British Institute of Radiology, and, highest honour of all, was elected president of the First International Congress of Radiology in 1925.

Outside his profession his hobbies were alpine photography and mountaineering. During the last fifteen years of his life he lived in retirement; but he still took an active interest in radiology and, as *doyen* of the radiologists, he attended many of the public functions until ill-health supervened. With his passing on January 16 at the age of seventy-seven, radiology has lost a leader, the last of the pioneers, who did much to establish this branch of medicine on a sound basis. A. E. BARCLAY.

Prof. T. R. Wilkins

NEWS has been received of the sudden death on December 10 of Prof. Thomas Russell Wilkins, professor of physics in the University of Rochester, New York. He was in his forty-ninth year.

Born in Toronto, Canada, he graduated at MacMaster University and came to Great Britain for post-graduate work at Cambridge. Before going to Rochester he held teaching posts at the University of Chicago, and at Brandon, Canada.

When the Institute of Applied Optics was founded at Rochester in 1928, Wilkins was placed in charge, and the success of the Institute owed a great deal to his interest and enthusiasm. His main scientific interests were always, however, in the realm of atomic physics, and he recently relinquished the optics post in favour of Prof. Brian O'Brien.

Wilkins was an enthusiastic research worker and his main line consisted in the study of cosmic ray and radioactive processes with the aid of photographic emulsions, a technique to which he made notable contributions, but not without long and laborious hours at the microscope.

Prof. K. F. Wenckebach

PROF. K. F. WENCKEBACH, an eminent Viennese physician and a founder of modern cardiology, whose death has recently been announced, was born at The Hague on March 24, 1864. After serving as an assistant at the Institute of Zoology and Pathology of Utrecht, he was appointed professor of internal medicine at Groningen in 1901, where he remained until 1911, when he was transferred to the corresponding chair at Strassburg. He held this post until 1914, when he was appointed professor of medicine at Vienna, retiring in 1929. He at first devoted his attention to embryology, but his subsequent work, for which he is best known, was concerned with the pathology and clinical aspects of cardiovascular disease and particularly cardiac arrhythmia. In 1920, in association with Prof. Jagic, he founded the *Wiener Archiv für innere Medizin*, of which his students offered him a *Festschrift* on the occasion of his retirement in 1929. During the occupation of his chair at Vienna he attracted a large number of practitioners and students interested in cardiology. He had many friends in Great Britain, where he was elected an honorary fellow of the Royal College of Physicians in 1928 and of the Royal Society of Medicine in 1930. J. D. ROLLESTON.

WE regret to announce the following deaths:

Sir Frederick Banting, K.B.E., F.R.S., professor of medical research in the University of Toronto, on February 21, aged forty-nine.

Prof. William J. A. Bliss, emeritus professor of physics in the Johns Hopkins University, on December 27, aged seventy-three.

Dr. J. G. Priestley, reader and demonstrator in clinical physiology in the University of Oxford, on February 9.

NEWS AND VIEWS

Charles Chree Medal and Prize

THE Charles Chree Medal and Prize, founded by Miss Jessie Chree in memory of her brother, the late Dr. Charles Chree, is to be awarded biennially to men of science who have contributed to the advancement of knowledge in those subjects in which Dr. Chree was particularly interested, and to which he had made signal contributions. The responsibility for, and the administration of, the award has been placed by Miss Chree in the hands of the Physical Society, and the Council of the Society has made the first award of the Medal and Prize to Prof. Sydney Chapman. Many minds in many countries have contributed to the advancement of the science of geomagnetism, and there are few branches of physics in which international co-operation is more desirable. British physicists have played a full part in the development of the science—Norman, Gilbert, Halley, Sabine (may we claim Lamont ?), and Chree himself, are outstanding names.

Prof. Chapman's contributions to the science are many and distinguished. His investigations of the diurnal variations and the separation of the solar and lunar effects have involved the handling of a mass of observations the magnitude of which has been well described as appalling. Prof. Chapman has analysed these observations with characteristic skill, devising new methods for the attack on this vast mass of data. Very important additions to our knowledge of the mechanism of the variations have resulted from Prof. Chapman's work. His analyses of the changes occurring in magnetic storms have resulted in a corpuscular theory of the origin of the storms. He has made weighty contributions to the critical literature of the subject and his latest volume, "Geomagnetism", written in collaboration with Prof. Bartels, is likely to remain for a long time the most detailed and authoritative treatment of the subject. The motto, *Sol rotatur magnetica respondet terra,* appears on the reverse of the Chree medal. This is a fitting comment on one aspect of the work of the recipient of the first Chree Medal.

Mrs. C. Neville-Rolfe, O.B.E.: Snow Medallist

As announced in NATURE of January 25, p. 114, Mrs. Neville-Rolfe has been awarded the Snow Medal by the American Social Hygiene Association. The medal is given annually for distinguished services to humanity. This was the first time the medal has been awarded outside the United States, and the only occasion on which it has been given to a woman. Mrs. Neville-Rolfe has been not without honour in her own country, but her qualities of courage and service have been, perhaps, more clearly seen by those interested in the promotion of social welfare in the great American republic. She is the eldest daughter of the late Admiral of the Fleet, Sir Cecil Burney, Bart.; her husband is Commander Clive Neville-Rolfe, who is at present on active service; while her brother is Commander Sir Dennistoun Burney, Bart, also on active and special service. Courage, therefore, comes naturally to her, and during the War of 1914–18 she saw where certain work was necessary, where no one else was doing it. It was not easy or popular work, and brought a good deal of prejudice to those who formed what is now known as the British Social Hygiene Council to fight one of the most serious and insidious forms of illness which, during and after the War of 1914–18, created considerable havoc both among individuals and homes in Great Britain.

Since that time, Mrs. Neville-Rolfe has been distinguished in pioneering effort, she has covered the whole country of Great Britain, lecturing, interviewing and organizing. She has taken her message overseas to Malta, Cyprus, India, Malaya, Hong Kong and the West Indies, and the Colonial Office has shown its appreciation of her work. She has visited and lectured in the United States, and is widely known as an eloquent and impressive speaker and as a pioneer in social welfare. It is good at this time to see that British and American people and organizations are appreciating each others qualities of service, and the bestowal of the Snow Medal on such an outstanding woman of Great Britain by the American Social Hygiene Association is a gratifying proof of this development.

Education in Social Hygiene

WHILE various professional organizations are interested in the vocational aspects of biology in education, and others are associated with certain special parts, it has been left to the Educational Advisory Board of the British Social Hygiene Council almost alone to concern itself with the value of biology as a medium of genuine education for people of all types and of all ages. Over the last three years, during which he has held the position of education officer to the Board, Mr. T. H. Hawkins has been working for a more generous appreciation of biology in the schools. His work has brought him into constant touch with educational authorities in all parts of the country, and much of his time has been taken up with conferences and discussions of problems of teaching technique. In recent months he has been active in the new movement for the service of youth, giving talks to adolescent boys on personal development and human biology. His position has been one calling for personal initiative, human insight, knowledge of public administration, and ability to get on with people of all shades of opinion.

Now, in relinquishing his post to take up an educational appointment in Trinidad under the Colonial Office, he is presented with a fresh field for his endeavours, in which problems of human biology appear in a clearer light than they do at home, even if differing only in degree. His experience of biology in education in England should help to give a fresh interpretation to teaching practice in the Colonial Empire. Mr. Hawkins is to be succeeded by Mr. H. C. Bibby. Mr. Bibby entered Queens' College, Cambridge, in 1931 and became College Prizeman in 1933, graduating in 1935. He has examined the flora of the hot springs of Iceland, and was awarded the degree of M.Sc. of the University of Liverpool for ecological research. He is the author of research papers and nature study articles. He has been science master in Oulton School, Liverpool, and senior biology master in Chesterfield Grammar School. He has the advantage of considerable experience in organizing camps and in various other forms of youth work. His appointment to Mr. Hawkins's important though difficult post seems a very happy one.

Presidency of the Institution of Mechanical Engineers

MR. ASA BINNS, the retiring president of the Institution, was born in Keighley, Yorkshire, in 1873, and was educated at the Grammar School, Keighley, and at the University of Leeds. His workshop training was obtained at the works of Messrs. Tannett Walker and Company, Leeds, and Messrs. Cole, Marchent, and Morley, Ltd., Bradford. After a period as draughtsman in Ipswich with Messrs. Ransomes, Sims, and Jefferies, he joined the staff of the Hull docks of the then North Eastern Railway in 1898, thus beginning an association with dock work which has since been continuous. A few years were spent with the Admiralty Works Department, and in 1906 Mr. Binns was appointed to the London and India Docks Company, and remained with the Company's successor, the Port of London Authority, until his retirement from the post of chief engineer in 1938, when he was retained as consultant. He is now consultant to Messrs. Rendel, Palmer, and Tritton, consulting engineers. He has been a member of the Institution of Mechanical Engineers since 1902. He contributed a paper on "Recent Developments in the Mechanical Equipment of the Port of London Authority" (*Proc.*, 122, 575; 1932) which was presented in May 1932 at the spring meeting of the Institution in London. Mr. Binns became a Whitworth exhibitioner in 1896.

Mr. W. A. Stanier has been elected to succeed Mr. Binns as president of the Institution of Mechanical Engineers. He has been a member of Council of the Institution for many years. He served his apprenticeship with the Great Western Railway at Swindon, and reached the position of principal assistant to the Chief Mechanical Engineer of that Company. His outstanding ability as a locomotive engineer was emphasized by a striking decision of Lord Stamp in appointing him chief mechanical engineer of the London, Midland and Scottish Railway, straight from his position as principal assistant at Swindon. It is particularly fitting that the chief locomotive engineers of Great Britain should follow their famous predecessor, George Stephenson, in the president's chair.

The Right Hon. Lord Harlech, G.C.M.G.

WHEN Lord Harlech takes up the office of High Commissioner in South Africa, to which his appointment was announced on February 21, he will enter upon his duties with a long experience of affairs and a judgment matured and affirmed by an intimate knowledge of the problems of British dependencies, and more especially of those of Africa, such as has been possessed by none of his predecessors in this high and important position. As the Hon. W. G. A. Ormsby-Gore, after serving as intelligence officer in the Arab Bureau and assistant political officer on the staff in the Middle East during the War of 1914–18, and holding several minor but important political appointments in the early years which followed the armistice, he became successively Under-Secretary of State for the Colonies, Postmaster-General, First Commissioner of Works and Secretary of State for the Colonies. In the office last named he brought to the problems of the colonial dependencies the firm conviction that scientific study and the application of the results of scientific research are essential to promote the prosperity of the Colonies themselves, and advance the interests and well-being of the inhabitants, whether European or indigenous.

Lord Harlech's acquaintance with conditions in the dependencies, gained by a personal inspection in most of them, was wider in range than that of any of his predecessors in office, and where Africa was concerned was reinforced by the detailed knowledge which had come with his experience as chairman of the East African Parliamentary Commission of 1924, and as the British representative on the Permanent Mandates Committee of the League of Nations. Lord Harlech's retirement from office after the death of his father in 1938, owing to his increased responsibilities, was felt by his colleagues and by all concerned with or interested in Colonial administration to be a great loss to the public service. His solicitude for the antiquities of England and Wales, and his services to British archæology while First Commissioner of Works, must be passed over here, but they are well known. Lord Harlech is an elected trustee of the British Museum and chairman of the governing body of the School of Oriental Studies in the University of London. He has also served as president of the Geographical Association and of Section E (Geography) of the British Association, as well as vice-president of the Museums Association.

Materials for Pest Control

IN 1937, several national industrial organizations, being impressed by the disturbing frequency of infestation of warehouses, granaries, mills and other structures of high capital value, and of ships, lighters, rolling stock, sacks and all other equipment essential to storage, process and transport, as well as by the heavy loss in value and destruction of foodstuffs, etc., set up an informal conference, under pledges of co-operation, with the object of establishing improved conditions. Infestation not being inherent in the commodities but being introduced in the links of the chain of trade, it was clearly essential to get general agreement on concerted action. Where standards were low or absent, proof was not lacking that there was a constant injection of infested commodities into the trade stream. At the outset it was recognized that control of the condition of the country's imports would have to commence in the countries of export, and that the aid of Government was necessary. It was also recognized as a first essential in that direction that definite indication should be given that the house here was being put in order. The most important and easiest step was that ordinary principles of cleanliness should be inculcated. This could be achieved largely by the exercise of commercial prudence. The owner of the commodity and the owner of the structure or equipment could be more mindful of their duty to each other, and the force of competition could be used to raise standards. Restraint on landing and isolation of fouled commodities again were really matters of commercial prudence, but as the most desirable precautions, if left to voluntary effort, could be offset by the recalcitrant or indifferent, something more substantial than the play of commercial prudence was needed. There remained the respective parts of the applied biologist and the chemist. Control of infestation of stocks or structures necessitated prolonged research. In this respect it was fortunate for the conference that these very matters had for a long time past been the special preoccupation of the Stored Products Laboratory of the Imperial College of Science and Technology; although it was to be regretted that that work in more recent times had suffered greatly and been circumscribed by lack of recognition.

The conference laid its problem before the Government early in 1938, and by the end of that year, decision had been taken for the establishment of a permanent research and advisory organization under the Department of Scientific and Industrial Research, industry making substantial grants towards the cost. The Department accepted the generous offer of the Imperial College to place the Stored Products Laboratory at Slough available, and the new organization inherits the benefit of the past work of the laboratory. The Department also established the Standing Conference of Co-operating and Contributing Industrial Organisations, and appointed as its chairman Mr. W. McAuley Gracie, the chairman of the former informal conference and the initiator of the industrial effort. Prof. J. W. Munro, the former director of the laboratory, has become the consultant to the Department, whilst retaining his chair in the College. This desirable conjunction of science and industry was effected prior to, and the organization was available at, the outbreak of war. In the course of the industrial investigations it has become apparent that immediate attention should be given to the establishment of a comprehensive case for guidance in production, research and application as relating to insecticides, fungicides, raticides and repellents for all purposes. Several scientific advisers to and in Government Departments have been consulted, and they fully agree as to this. Certain sectional pieces of work have been done, and available information can be lifted out of dormancy, but there are gaps to be filled and a general harmony to be established, so that economic decisions may be taken and lines of research indicated. Mr. Gracie has requested Mr. W. V. Blewett, who has been released by Imperial Chemical Industries, Ltd., for this purpose, to carry out at once an economic and technical survey of the demand and production of these materials, with special reference to the potentialities and requirements of the British Empire and friendly States. Communications should be addressed to Mr. Blewett, at 42 Hamilton House, 155 Bishopsgate, London, E.C.2.

The Universities and Man-Power

AT the annual meeting of the Court of Governors of the University of Birmingham, the Vice-Chancellor, Dr. Raymond Priestley, paid a tribute to the attitude of the Government in recognizing the importance of the part the universities can play in the war-time economy of Great Britain. This has been directed towards the avoidance of the waste of young men of high educational attainment and intellectual promise which was so lamentably characteristic of the War of 1914–18. Dr. Priestley regards this attitude as "one of the few signs of progress we can see in a backslidden generation". But in the last few weeks, things have taken a turn for the worse. In times of crisis, when the immediate needs fill the foreground, there is a real danger that we may take a too shortsighted view. The stream of science, and applied science, graduates has so far been undammed; the trouble here is the great increase in the demand. But Dr. Priestley wonders now whether we have been wise in diminishing the flow of graduates in commerce, art, and law. The Government clearly has not changed its university policy, and intends to safeguard the situation as well and as promptly as it can.

"The real menace to our future is the air training scheme. No one in his senses will grudge to the R.A.F. to-day the lion's share of the flower of the nation's youth. Nevertheless, this scheme, reaching, as it does, right down into the schools, is the real danger the universities face to-day. Its success is a measure of the essential soundness, the grit, the adventurous spirit and the imagination of British youth. But this does not decrease the universities' dilemma, as they foresee the loss of their raw material for 1942 and later war years. Some of these lads, outstanding in character and intellect, who are to-day flocking to the R.A.F., should be saved from their own enthusiasm. For the sake of the nation's future, they should be directed into the universities".

Government Grant to Universities

SPEAKING in reply to a question by Mr. K. W. M. Pickthorn (University of Cambridge), Sir Kingsley Wood, Chancellor of the Exchequer, recalled that, in view of the vital part played by the universities in the life of the community, the importance of maintaining so far as possible the standards of university education and the essential contribution which the universities are making in a variety of ways towards the national effort, it was decided to maintain the provision for the current year at the same level as that of 1939, namely, £2,149,000. These considerations, he said, have lost none of their force, and despite the increasing strain on the national finances the Government, after considering a report from the University Grants Committee, have reached the conclusion that if the universities are to continue their present contribution to the national effort the provision for 1941 must be maintained at the existing level. He expressed the hope that local authorities will take similar action.

Precautions against Blister Gas Attacks

As a precautionary measure, which is being taken to cope with the possible use of blister gas by the enemy in aerial attacks on Great Britain, pharmacists are to be asked to provide supplies to the public of 'bleach cream'. The Ministry of Home Security, which has been in collaboration with the Pharmaceutical Society, is responsible for the scheme. Briefly, the Ministry has invited all proprietors of pharmacies, by a letter addressed to each one of them, to make 'bleach cream' available for members of the public in the event of blister gas being dropped in the vicinity of their pharmacies. The plan is quite simple; it is that the proprietor of each pharmacy, having been provided by the local authority with two enamel pails and a supply of 'tropical bleach' for the preparation of bleach cream, should, when and if gas is first used, place the pails furnished with cream on the pavement outside his shop with a poster instructing the public how to apply it. No charge would be made to the public, and it has been agreed with the Pharmaceutical Society that pharmacists should be asked to perform this service without payment as part of their contribution to the national effort.

An Ichthyosaurian Fossil

ACCORDING to a report published by the daily Press, a nearly complete skeleton of an Ichthyosaurian, or fish-shaped fossil reptile, has been found in the shaft of the Hermann Göring Mine in the northern Harz Mountains. It is to be studied by Prof. J. Weigelt, of Halle, who estimates its length as 5·10 metres, or nearly 17 feet. Such well-preserved large skeletons are very rare and difficult to extract from the rock in a perfect state. The largest Ichthyosaurian skeleton in the British Museum, which was obtained from the Lower Lias of Lyme Regis, Dorset, would measure about 24 feet in length when it was complete. Several known Ichthyosaurian skulls from the Lias belong to individuals which must have been at least 30–40 feet long. One of the finest of these large skulls, from Lyme Regis, is exhibited in the rooms of the Geological Society of London at Burlington House.

Classification of Ships and Machinery

THE Thomas Lowe Gray Lecture to the Institution of Mechanical Engineers on January 24 by Dr. S. F. Dorey was on the "Progress in Marine Engineering as Influenced by the Classification of Ships". The classification of ships sprang out of the ancient practice of marine insurance, and has been in vogue for nearly two centuries. There are many classification societies; but the best known is Lloyd's Register of Shipping of which Dr. Dorey is the chief engineer surveyor. These classification societies serve the interests of shipowners, shipbuilders, engineers, underwriters and others, and each of them has rules relating to the construction and maintenance of ships and their machinery. Giving a sketch of the development of marine machinery since the earliest steamboats, Dr. Dorey traced the rules by which Lloyd's Register has influenced progress. From the first specification for machinery, right through the period of its construction and at regular periods during its life, Lloyd's surveyors have duties to perform, and the whole shipping industry owes much to the impartial and exceptional way those duties are performed. From its very constitution a classification society is strictly impartial; it is a form of voluntary control of an industry by the industry for the general well-being.

Factory Canteens

THE Factory (Canteens) Order of the Minister of Labour, whereby all factories doing Government contract work and employing 250 persons are required to provide canteen facilities either in or near the workshops, has opened up new problems to the management of factories (*Electrician*, Jan. 17). In the first place, factory meals will, of necessity, be inexpensive, and of the various cooking processes involved, boiling and steaming will be in preponderance for such items of diet as stews, steamed puddings, rice and vegetables of various kinds. Ample steaming oven accommodation must therefore be made for the large quantities of steamed food, and steam boiling pans for greens, stews, etc. Electric cooking has the advantage that the air is not vitiated by the products of combustion, and ventilation problems are, therefore, usually less acute. The usual number of air changes per hour normally allowed for a kitchen is of the order of 20–60; this could be modified, depending on the provision for natural ventilation. In using electricity for thermostaically controlled instantaneous boilers to deliver water near boiling point, it is best to arrange that the demand occurs during the peak period of the load on the public power station.

Molybdenum and Tungsten in the Caucasus

IT is announced by "Russia Today" Press Service that large molybdenum and tungsten works have been opened recently in Kabardino-Balkaria, in the Caucasian mountains. The plant is situated at the foot of Mount Tyrny-Auz. Soviet geologists began to prospect for ores on this mountain in 1934. At an altitude of 9,850 ft. they discovered large deposits of rich molybdenum and tungsten ores. Owing to the situation of the Tyrny-Auz deposits, however, the extraction of the ores has presented a difficult problem, and local weather is severe. Everything about the workings is mechanized. The ore, which is extracted by means of electric drills, is brought away from the face by electric trains, sent to the surface by conveyer belt and lowered to the works at the foot of the mountain by cable hoists. The ore mine has four electric power stations and a central air-compressing station. There is an electric sub-station underground. The nearest centre to the new works is Nalchik, capital of Kabardino-Balkaria.

Detection of Toxic Gases

We have received a copy of Leaflet No. 12, "Methods for the Detection of Toxic Gases in Industry: Organic Halogen Compounds" (H.M. Stationery Office, 1940. 2*d.* net). Ten substances are covered, including tetrachloroethane, pentachloroethane and carbon tetrachloride. One of the most toxic of the group is tetrachloroethane. The method of detection is by the use of a special lamp burning pure alcohol in a supply of the air under test. The halides are decomposed and react with a small copper screw in the nozzle of the lamp, giving a green coloration to the flame.

Marie-Alfred Cornu, For.Mem.R.S. (1841-1902)

On March 6 occurs the centenary of the birth of the distinguished French physicist, Marie-Alfred Cornu, who for thirty-five years held the chair of physics at the Ecole Polytechnique and who in 1896 was elected president of the Paris Academy of Sciences. Born at Chateauneuf, near Orleans, he had a brilliant career as a student at the Ecole Polytechnique and the Ecole des Mines, and was made a professor at the former at the age of twenty-six. His investigations carried out in the next ten or fifteen years raised him to the highest rank of experimentalists. Using Fizeau's methods he re-determined the velocity of light; with Baille, in the cellar of the Ecole Polytechnique, he re-determined the density of the earth, and among his memoirs of this time were some on the theory of electrostatics in which he explained the potential theory of Gauss and Green, then little known in France. His later work included valuable researches in spectroscopy. He was admitted a member of the Paris Academy of Sciences in 1878 as successor to A. C. Becquerel, and in the same year received the Lacaze Medal, and also the Rumford Medal of the Royal Society. In his own country he served on the Bureau des Longitudes, and as president of the International Commission of Weights and Measures. He was a foreign member of the Royal Society, and an associate of the Royal Astronomical Society. As Rede Lecturer at Cambridge in 1899, he discussed "The Wave Theory of Light and its Influence on Modern Physics". He was not only a successful experimentalist and a leader in scientific thought, but also a great teacher. He died on April 11, 1902. Three years later the French Physical Society struck a medal in his honour.

The Night Sky in March

The shortening night reaches equality with the day at the spring equinox, March 21d. 0h. U.T. The moon is full on March 13 and new on March 27. A partial lunar eclipse occurs at the full and an annular eclipse of the sun at the time of new moon, but both eclipses are invisible from Great Britain. A notable occultation takes place on March 5, when both the disappearance and reappearance of α Tauri (Aldebaran) can be favourably observed subject to weather. As seen from Greenwich, the disappearance of the star behind the moon's unilluminated edge (moon near first quarter) is at 19h. 16·1m. at position angle 108° from the north point of the moon's image; the subsequent reappearance is at 20h. 29·1m. at 242°. On March 8, λ Geminorum is also occulted, the disappearance seen from Greenwich being at 21h. 20·4m. at position angle 97° (Add 1 hour to all these times to read in Summer Time.)

Of the planets visible this month, Jupiter and its close companion, Saturn, are in the western sky at sunset; they are not far from the moon's slender crescent on March 3 and 30. Mars continues as an early morning star, in the constellation of Sagittarius. The planet is moving about 3 minutes of Right Ascension per day eastwards amongst the stars. Venus and Mercury are now stars of the dawn, being in conjunction with each other on March 3 at 13h. Mercury reaches greatest western elongation (28°) on March 25, but Venus is drawing towards the sun's place until superior conjunction on April 19. In mid-March, Sirius souths about 1 hour after sunset.

As night sets in, the bright stars of the familiar winter constellation are declining westwards. Amongst the less spectacular constellations east of the meridian is Coma Berenices. This constellation contains a loose cluster of stars which, about March 15, comes to the southern meridian at 2h. summer time at an altitude of 65°. East of this cluster is the position of the north galactic pole. A long-exposure photograph (200 minutes) taken with the 100-inch reflecting telescope at Mount Wilson "records fully as many recognizable nebulæ as stars" (Hubble). The farthest of these nebulæ recorded on the photograph are thought to be at an average distance of the order of 500 million light years. Thus in the general direction of the galactic poles—unobscured by the vast gas and dust clouds of our stellar system—we look out into remotest space.

Announcements

On medical advice, Sir Edwin Butler, formerly director of the Imperial Mycological Institute, has resigned from the secretaryship of the Agricultural Research Council.

Dr. Franz Verdoorn, editor of *Chronica Botanica*, has been appointed research associate in the Farlow Herbarium, Harvard University.

The Rockefeller Foundation has agreed to continue until the end of 1941 its grant of £1,200 a year for research in cellular physiology at the Molteno Institute, University of Cambridge, under the direction of Prof. D. Keilin.

In 1938 there were 15,111 cases of smallpox in the United States. Of these, 14,106 occurred in the States north of Ohio and west of Mississipi, where vaccination is not compulsory.

Action of Sulphonamides and their Derivatives on Bacteria

THE sulphonamides constitute a group of therapeutic agents of the highest importance in the treatment of disease, yet at the present time comparatively little is known concerning the precise nature of their mode of action upon micro-organisms in general. In this connexion Long and Bliss in their work "The Clinical and Experimental Use of Sulphanilamide, Sulphapyridine and Allied Compounds" quote: ". . . for the time being one must be content with the simple conception that these sulphonamido preparations inhibit the growth of susceptible micro-organisms in the body and in the test tube". In my investigations on the *in vitro* mode of action of sulphanilamide I have discovered a hitherto unknown yet easily demonstrable reaction which throws considerable light upon the mechanism of the anti-bacterial activity of this drug and renders it necessary to modify the above statement of Long and Bliss. In this preliminary communication I wish to place on record a brief summary of my researches during the last twelve months.

It is a well-known fact that the group of organisms exemplified by *B. subtilis, B. mycoides, B. megatherium, B. mesentericus* exhibit a pelliculous growth on the surface of the liquid culture medium. I have found that members of this group exhibit an abnormal behaviour in the presence of sulphanilamide and allied compounds of the sulphonamido type in as much as the pellicle formation is inhibited or completely suppressed. Concentrations of sulphanilamide of 1 : 100 to 1 : 3000 retard the rate of growth of *B. subtilis*, but even in the presence of this high concentration of the drug an excellent growth of the organisms develops after some time, although pellicle formation does not take place. In dilutions greater than 1 : 3000, sulphanilamide exerts no retarding influence on the rate of growth of the bacteria, but, in spite of the normal rate of growth, there is complete suppression of pellicle formation which persists down to dilutions of sulphanilamide as great as 1 : 50,000 to 1 : 100,000. As the dilution of the drug is increased beyond 1 : 100,000 there is observable a gradual development of pellicle. I have found, moreover, that the degree of inhibition of pellicle formation is strictly parallel with the degree of inhibition of spore formation. The inhibition and ultimate suppression of sporulation is indicative of a subnormal bacterial metabolism, and from this it must be inferred that the bacteria are living in an asthenic state. In addition, I have observed that the ability to inhibit and suppress pellicle formation is not limited to sulphanilamide alone, but is also possessed by a multitudinous number of diverse chemical compounds; in fact it is possessed in varying degree by all substances which exert an injurious effect upon the bacterial life.

Up to the present time it has been possible to demonstrate two types of anti-bacterial activity, namely, bactericidal and bacteristatic. However, it is now possible to extend this and render demonstrable in a precise yet simple manner a third state of anti-bacterial activity which I have designated a bacteriasthenicizing activity. Under the bacteriasthenicizing influence the bacterium exhibits a normal rate of growth but a subnormal metabolism, that is, the organism continues to live and grow in a state of bacteriasthenia.

It is a well-known fact that chemical change in the structure of the sulphanilamide molecule, such as the introduction of N_1 and N_4 substituents or modification of orientation of the amino and sulphonamido groups, changes in a precise and definite manner the *in vivo* anti-bacterial activity. By experimenting with all the well-known synthetics of the sulphonamido group I have found that in the same way alteration of the chemical structure of the sulphanilamide molecule is accompanied by a modification in the ability to inhibit pellicle formation of *B. subtilis* and, moreover, that this modification is strictly parallel with the modification of the *in vivo* anti-bacterial activity. This is demonstrated in the accompanying table.

Drug	*In vivo*	*B. subtilis* reaction
Sulphanilamide	Very active	Very active. Pellicle formation suppressed down to sulphanilamide concentration of 1 : 100,000
Sulphanilic acid	Slightly active	Slightly active. Pellicle formation suppressed only by concentrations of sulphanilic acid greater than 1 : 4000
N_4 acetyl-sulphanilamide	Inactive	Inactive. Good pellicle formation in concentrations of drug as high as 1 : 1000

All active compounds at present in therapeutic use, for example, sulphanilamide, albucid, sulphapyridine, soluseptazine, etc., are active in the new reaction, that is, they completely suppress pellicle formation down to dilutions of the drug of 1 : 50,000 to 1 : 100,000.

Moreover, it is a well-established fact that the anti-bacterial activity of sulphanilamide is inhibited by the presence of *p*-aminobenzoic acid both *in vitro* (Wood) and *in vivo* (Selbie). A parallel phenomenon is observable in the new reaction, namely, although high dilutions of sulphanilamide suppress pellicle formation, the addition of *p*-aminobenzoic acid enables copious pellicle formation to take place even in high concentrations of sulphanilamide.

The complete results of the researches outlined above, with results obtained *in vitro* in the presence of blood and serum, and together with observations on the bacteriasthenicizing activity of the blood and serum of patients undergoing sulphonamide therapy, will be shortly published.

Vitamin Content of Salmon

The tables of the vitamin content of foods of Fixsen and Roscoe[1] are in constant use in assessing the vitamin value of diets. Our attention, however, has recently been directed particularly to salmon. The vitamin A concentration of body oil and flesh oil is there given as 4,400–52,500 and 0–20,480 international units per 100 gm., while the vitamin D concentration of flesh oil is listed as 9,500 international units per 100 gm., and the vitamin D content of salmon flesh at 200–800. The ascorbic acid content given is 89·9–215·6 mgm. per 100 gm. of flesh. These vitamin C figures are higher than any reported for oranges and lemons and equal those given for varieties of blackcurrant, noted for their antiscorbutic properties. Taken together with a calorific content thrice that of orange juice, these values suggested that salmon might be regarded as deserving of precedence over the citrus fruits for import space.

Confirmation of these figures was desirable. Since most of the salmon eaten in Great Britain is tinned, twelve different brands were purchased in the open market, together with a chilled salmon weighing about 24 lb. This was kept in a cold store until a few minutes before the analyses were made. The accompanying table shows the results of the analyses on these.

Sample.	Vitamin A (blue value).	Vitamin B (I.U. per 100 gm.).	Vitamin C (mgm. per 100 gm.).

5. ,, ,,	,,	11	,,
6. ,, ,,	,,	8	,,
7. ,, ,,	,,	11	,,
8. Scottish (probably)	,,	8	,,
9. ,, ,,	,,	8	,,
10. ,, ,,	,,	10	,,
11. 'Foreign'	,,	8	,,
12. Japanese	,,	8	,,
13. *Chilled Salmon.*			
a. Middle cut	nil	76	9
b. Tail cut	nil	86	9
c. Liver	860		10
d. Roe (hard)	30	190	21
e. Intestine	33	38	10
f. Pancreas	154	34	6
g. Heart			8
h. Gills	nil	nil	4

Vitamin A was determined by hydrolysis of the fish sample in methyl-alcoholic potash and measurement of the antimony trichloride 'blue value' calculated to a 20 per cent solution of the original sample on the non-saponifiable residue. No carotene was detected. Vitamin B_1 was determined by the thiochrome method; vitamin C by titration with 2·6 dichlorophenol indophenol.

A representative sample of the whole material from one of the tins listed above was assayed biologically on chicks by the B.S.I. standard radiographic-technique for vitamin D_3. It gave a figure of 600 units per 100 gm. of flesh with fiducial limits at $P = 0·95$ of 83–119 per cent. This agrees with Fixsen and Roscoe's figure quoted.

From this work, it appears that, although fresh salmon may contain the large vitamin stores attributed to it, the material that reaches the table of the British housewife is far from being as rich in vitamins A and C as hitherto published figures would suggest.

Weather, Wild Birds and Home-grown Food

The effects of the severity of the winter of many years back on wild birds have been described by various writers from 1408 onwards, but coming to more recent times we have the comprehensive account given by James Hardy and others[1] for the winter of 1879–80, that of A. W. Preston[2] for 1890–91 and other references to the winter of 1894–95. Still more recently we have the excellent account by Jourdain and Witherby[3] of the disastrous effects of the winter of 1894–95, and finally the very full and valuable account of the effects of the particularly severe winter of 1939–40 given by Ticehurst and Witherby[4].

It is unnecessary here to detail the enormous reductions that have taken place in our wild bird fauna. They are very serious and the repercussions will be of a far-reaching nature.

Those interested in economic biology know what an enormous amount of home-grown food was destroyed by injurious insects and rodents in 1917 and 1918, and there seems no reason for supposing that any but similar conditions will prevail in 1941 and 1942, unless some wise and well thought out action is taken quickly.

Writing in 1918[5] I have pointed out that "All who take an interest in the ways and habits of wild animal life must have been struck by this curious coincidence—namely, during the spring and summer of 1917, very many of our commoner species of wild birds were apparently rare, and injurious insects and rodents were particularly abundant; during 1918 the same phenomenon was still more noticeable, the insects being exceedingly abundant, in many districts sufficiently numerous to constitute a plague. As a result of this dislocation of the so-called balance of nature an enormous amount of home-grown food has been lost".

To-day it is not enough for the farmer and fruit grower to grow abundant crops if such cannot be harvested clean and free from disease. Every year vast quantities of such food are destroyed by injurious insects and rodents, and this year and next, owing to the great reduction in our wild bird population, that amount will increase to an enormous extent, and although we are increasing the acreage cultivated, the sum total, in very many cases, instead of being more, will be less.

In view of the seriousness of the situation, I suggest that the destruction or taking of any wild birds or their eggs in Great Britain and Northern Ireland from now until the end of 1942 (the following species excepted—house sparrow, starling and wood-pigeon) should be prohibited during 1941 and 1942, and the results of such action carefully reviewed and any further action considered at the end of 1942.

Conical Refraction in Naphthalene Crystals

THE birefringence of many organic crystals of the aromatic class is large, and when the intermediate index differs widely from the upper and lower indexes, the angles of internal and external conical refraction assume very high values. These angles in naphthalene, for example, are both about 13° 45′, which may be compared with 1° 54′ and 1° 44′ respectively in the classical case of aragonite. By fusion followed by very slow solidification, it is fairly easy to obtain transparent blocks of naphthalene and other aromatic compounds. When suitably cut and mounted between glass cover-slips, naphthalene crystals exhibit the phenomena of conical refraction in a very striking way, and enable their features to be critically examined.

The photographs reproduced with this note are the images of a fine illuminated pinhole held against the face of a naphthalene crystal 2 mm. thick and viewed through it in the appropriate direction. In the first of the series, the pinhole is seen in perfect focus and appears as a very sharp and perfect circle. The three other pictures illustrate the effect of moving the focus away from the pinhole, until, finally, in the last picture, the second surface of the crystal is in focus. The central bright spot seen in the fourth picture is actually an image[1] of the fine pinhole used, and appears at the point where the axis of single-ray velocity meets the rear surface. This bright spot continues to be the most conspicuous feature in the field for a great distance behind the crystal.

CONICAL REFRACTION IN NAPTHALENE CRYSTALS.

It will be seen on a comparison of the first and second pictures that, at least in the case of naphthalene, *the so-called Poggendorf dark circle vanishes when the pinhole is seen in perfect focus.*

Temperature Dependence of Adiabatic Compressibility

IT is well known that the adiabatic compressibility β_φ of a liquid increases fairly rapidly with rise in temperature. The rise becomes more rapid as the temperature increases. With many liquids the adiabatic compressibility increases by about 60 per cent for a rise of temperature from 0° to 60°, or $\frac{1}{\sqrt{\beta_\varphi}}$ decreases by 21 per cent. A large part of the high initial compressibility of ordinary liquids is connected with the nearness of the critical point liquid gas, for compressibility in the gas phase is high and at the critical point itself compressibility is infinite[1]. Hence the absolute value of the compressibility depends on how far the temperature is from the critical point.

The characteristic frequency of vibration of molecules in a liquid is given by

$$\nu = S\left(\frac{3N}{4\pi V}\right)^{1/3},$$

where S is the velocity of sound in the liquid and N and V are Avogadro's number and molar volume respectively[2];

$$\text{or } \nu = c\sqrt{\frac{V^{1/3}}{M\beta_\varphi}},$$

for a given liquid, where c is a constant and M the molecular weight.

In the light of the available data[3] on the compressibility of a number of liquids, the above expression has been examined in relation to its temperature variation, and it is found that the expression decreases linearly with temperature according to the relation

$$\sqrt{\frac{V^{1/3}}{M\beta_\varphi}} = k\,(\theta_c - \theta),$$

where θ_c is the critical temperature, θ is any temperature and k is a constant characteristic of the liquid. In the following table are given values of k for a number of liquids:

Liquid	k
Benzene	110·8
Carbon tetrachloride ..	77·5
Ether	121·8
Chlorobenzene	80·8
Toluene	92·6
Acetic acid	93·6

The expression does not hold for alcohols. It is also found that a fair estimate of the critical temperature can be made from the variation of the adiabatic compressibility with temperature.

Details will be published elsewhere.

Laws of Nuclear Structure Derived from Nuclear Spins

In 1935 and 1936 I directed attention[1] to a striking statistical property of atomic nuclear spins, namely, that the form of the distribution curve for spins of atoms with odd atomic weight depends upon whether the odd particle in the nucleus is a proton or a neutron. Since then, new and revised nuclear spin values have been reported for a number of atoms. The new distribution curves completely confirm the conclusions I then gave relating to the orbital and spin momenta of nuclear particles. Fig. 1 shows the new distribution for atoms with odd atomic number (odd nuclear proton) and Fig. 2 that for atoms with even atomic number (odd nuclear neutron). Shaded areas represent the number of atoms for which the reported spin values are doubtful but probable.

Nuclear spins are now known for eighteen pairs of isotopes in which both constituents have odd atomic weight. Eleven of these pairs (A) have odd atomic number (odd proton), the remaining seven pairs (B) having even atomic number (odd neutron). These isotope groups are :

GROUP A
Odd nuclear proton

Atom	Isotope	Spin
Cl	35 37	} 5/2
K	39 41	} 3/2
Cu	63 65	} 3/2
Ga	69 71	} 3/2
Br	79 81	} 3/2
Ag	107 109	} 1/2
Sb	121 123	} 5/2
Eu	151 153	} 5/2
Re	185 187	} 5/2
Tl	203 205	} 1/2
Rb	85 87	5/2 3/2

GROUP B
Odd nuclear neutron

Atom	Isotope	Spin
Mo	95 97	} 1/2
Cd	111 113	} 1/2
Sn	117 119	} 1/2
Ba	135 137	} 3/2
Xe	129 131	1/2 3/2
Yb	171 173	1/2 5/2
Hg	199 201	1/2 3/2

It will be noticed from these that there is another striking difference in distribution depending upon the nature of the odd particle. Apart from rubidium, *all* the members of group A have the *same* spin for both constituent isotopes. On the other hand, three out of the seven pairs in group B have *different* spins for the two isotopes, the heavier isotope having a greater spin. The exception, rubidium, is of particular interest, for the isotope 87 is radioactive and this is very likely to be the cause of the deviation.

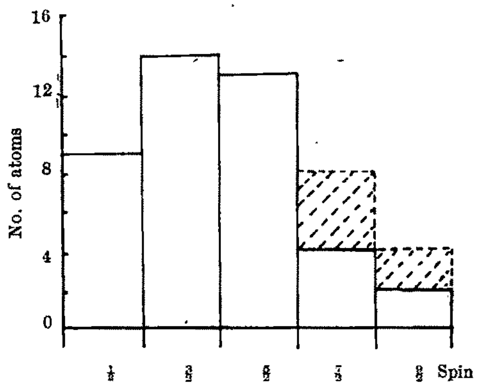

Fig. 1.
Odd proton.

In all these isotopic pairs the heavier constituent is formed from the lighter by the addition of a pair of neutrons. Both the curves and the additional data just given afford indirect support for Landé's odd particle theory of nuclear spin.

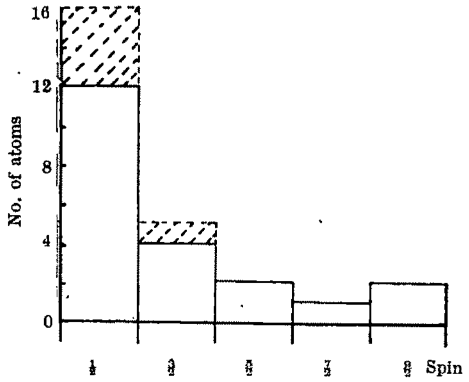

Fig. 2.
Odd neutron.

Three laws for nuclear structure can therefore be derived for stable odd atomic weight atoms :

(1) In stable atomic nuclei with an odd nuclear *neutron*, the spin and angular momenta of the lightly bound or odd particle(s) tend to *oppose* each other[1].

(2) In stable atomic nuclei with an odd nuclear *proton*, the addition of two neutrons does *not* alter the nuclear spin.

(3) In stable atomic nuclei with an odd nuclear *neutron*, the addition of two neutrons *may* increase the nuclear spin.

As a corollary to (2), it may be considered that when two neutrons are added in the presence of an odd proton, the neutrons set themselves with their spins in opposition.

RESEARCH ITEMS

Bronze Head from Ifé, Nigeria

The British Museum has recently acquired through the good offices of the National Art Collections Fund an example of the remarkable realistic art of Ifé, Southern Nigeria, in the form of a bronze head. This region of Southern Nigeria, which has long been known as the religious and cultural centre of the Yoruba people, possesses an ancient tradition of artistic accomplishment of a high order. It is distinguished by its realism from the generality of Negro sculpture, which is better displayed in diverse simplifications and conventionalizations of the human form than in strict fidelity to Nature. Hitherto, Ifé art has been represented in the British Museum only by a single original in the form of a terra-cotta head. In recent years a number of examples of the bronze heads have been found during building operations at Ifé, while the late Leo Frobenius collected several of the terra-cottas in 1911–12. In describing the British Museum acquisition, H. J. Braunholtz (*Brit. Mus. Quarterly*, 14, 4; 1940) states it is of exceptional ethnographic and æsthetic interest. It has evidently been cast by the *cire perdue* process and is now patinated to a green tint, though showing traces of red paint on the headdress, possibly a relic of painting of the whole. Parallel lines on the face represent a form of scarification still practised. Small holes surrounding the mouth and extending to the ears presumably were intended for the insertion of hair or other material to represent a beard and moustache. In vitality and sensitive modelling, it bears comparison with the finest sculpture of other times and countries. In date it can scarcely be later than the sixteenth century, when the art of Benin reached its highest peak.

Reproduction of Trout in New Zealand

A wide collection of material from sixty-four streams in ten river systems in the North and South Islands has enabled Derisley F. Hobbs to reach reasonably sound conclusions regarding the natural reproduction of the introduced brown trout (*Salmo trutta*) and rainbow trout (*S. irideus*) in New Zealand (*Fisheries Bull.*, No. 8, New Zealand Marine Dept., Wellington: Gov. Printer, 1940. 3*s*.). The conditions required by trout for spawning are very special, and are to be found in restricted areas even in streams with beds predominantly of gravel. The result is that all the suitable sites are used for redds by early spawners, and late spawners, rather than spawn in unsatisfactory materials, make use of already occupied sites. Mortality therefore arises from the actual displacement of the earlier eggs, or from the deposition of silt upon the earlier eggs by the later activities, for heavy losses in redds were found to be associated with the presence of excessive quantities of fine silty matter. The extent of losses caused by superposition of redds has not been measured, but apart from that, losses are extremely small in the majority of redds. Deaths before hatching vary from 3·20 to 12·86 per cent, with one extreme case of 29·29 per cent. Between the time of hatching and the emergence of the fry from the redds, the death-rate is exceedingly low; in only one of nine river systems did it exceed 1 per cent. The author discusses in a hypothetical way the question of optimum density and exploitable excess in these natural populations; but the validity from the practical point of view of the angler or fish conservator of such conclusions as he reaches is likely to be overshadowed by natural fluctuations and environmental influences generally.

Flight of an Insect

Under the title of "The Flight of a Dipterous Fly *Muscina stabulans* Fallen", F. S. G. Hollick of the Zoological Laboratory, Cambridge, describes the results of his investigations (*Phil. Trans. Roy. Soc.*, B, **230**; 1940). As a preliminary, a comparison was made between the flight system with the insect held stationary and in normal free flight, and the relationship of one to the other established. The resultant of those forces, which by action on the insect's body maintain or change its state of motion during flight, was taken as the criterion for comparison. The author exposed the insect, held stationary, to a stream of air in a wind tunnel and states that there are good grounds for believing that such a method is suitable for the further study of flight. By recording photographically the amplitude of the wing-beat for ten individuals inclined at 0°–45° to air flows ranging from 0 to 320 cm. per second, it was shown that the amplitude decreased with increasing air speed and inclination of the body axis. A study of the path travelled by the wing relative to the insect shows that when the insect is exposed to a stream of air the course of the downward beat is displaced forwards, so as to convert the elliptical track characteristic of wing movement in 'still air', into the figure of eight path, commonly associated with insect flight. This change of path traversed by the wings was found to be dependent upon the movement or position of the third antennal joint relative to the second joint, resulting from the action of the stream of air on the third joint and the arista. The usual flight attitude of the legs and the continued maintenance of wing vibrations when air was blown on the insect from in front, were also found to be dependent upon the integrity of this system. In the appendixes the author describes his method of mounting living insects for experiment, together with the design of an aerodynamic balance and that of a small wind tunnel.

Caytonia: A Gymnosperm

T. M. Harris has redescribed the fruits of Caytonia from the material in the Wonnacott Collection in the British Museum (*Ann. Bot.*, N.S. **4**, October 1940). As a result, *Gristhorpia nathorsti* is renamed *Caytonia Gristhorpi*, and further support is given for associating all three species of Caytonia with foliage of species of Sagenopteris. In his original account, Hamshaw Thomas described the fruits as curved structures terminating in a lip on the adaxial side, which was termed a stigma. Harris has now found pollen in the micropyles of fifteen specimens of *C. sewardi* and sixteen of *C. nathorsti*, and concludes that the lip in life must have bordered a slit through which the pollen could enter the structure, so that the pollination was definitely gymnospermous in character. This necessitates a mechanism by which the pollen is directed from the lip to the micropyle, particularly as pollen is not found freely in the cavity of the fruit. The state of preservation makes the solution of this problem difficult, but Harris points out that the peculiar barred structure of the mouth may result from the obliteration of converging canals running from the ovules to the mouth, and along which some 'pollination drop' mechanism may have conveyed the pollen. Harris concludes that Caytonia is a megasporophyll with pinnate branching, the pinnæ bearing ovules on their uncurved adaxial surfaces. This coincides with Thomas's first analysis of the structure: the later attempts to homologize the megasporophyll segments with carpels, or with the 'cupules' of the Corystospermaceæ, are deprecated.

Cross-lamination in Sandstones

A STUDY based on statistical analysis of cross-lamination in four Palæozoic sandstone units in northern Arizona—one of marine, two of deltaic and one of æolian origin—has been made by E. D. McKee, whose results are now published (*Amer. J. Sci.*, 238, 811–824; 1940). In the Tapeats sandstone (Lower Cambrian marine) the type of cross-lamination pattern consists of repeated layers, each containing series of short, uniformly sloping, laminæ truncated by flat surfaces above and below, and suggests a sinking basin in front of a delta. In the Supai formations (Permian deltaic) the beds are characterized by a series of sloping, even, lamination surfaces which dip uniformly from top almost to bottom, suggesting development on the advancing fronts of small local deltas. Comparable structures have been observed by the author over large areas of the present-day Colorado River delta. In the upper Supai sediments individual sets of sloping laminæ terminate laterally by interference from other sets and the resulting patterns resemble 'compound foreset bedding' due to interference of adjacent lobes. In the Conconino sandstone (Permian æolian) the structure consists of sloping truncated wedges and is devoid of flat-lying or horizontal layers such as characterize the formations mentioned above. Moreover, the maximum dip (33°) is higher than that of the others, and some of the low-angle slopes show a direction reverse to the normal, indicating depositional or erosion surfaces on the windward side of the dunes. The data collected also serve to determine the different directions of transportation among the various types of sediments considered.

Fermentation of Ceylon Tea

THE term 'fermentation' is understood in the tea industry to mean the enzymic process during which 'black tea' develops its aroma and colour. After harvesting, the partly dried leaf is broken up in a rolling machine, whereby some of the juices are worked out from the leaf and form a varnish-like coating on the surface. This rolling or crushing starts fermentation which may be allowed to continue for several hours. The initial green colour of the crushed leaf changes during this time to a coppery-red tint. The tea is then dried, cleaned and graded. It has been known for some time that this fermentation involves oxidation of polyphenols in which oxidases, peroxidases and catalases are concerned. The substrates include tannins, catechins and polyphenols (catechol, gallic acid) so that the whole process is very complex. Since tea leaf contains a much higher amount of polyphenolic substances than is usual in plant tissues, it would not be surprising if it contained also enzyme systems with rather specialized functions. J. Lamb and H. B. Sreerangacher (*Biochem. J.*, 34, 1472; 1940) now show that tea leaf preparations show marked specificity in the oxidation of ortho-dihydric polyphenols, without the activation of peroxidase, the primary oxidation products being probably orthoquinones. The system possesses the power of forming aniloquinones in the presence of quantities of potassium cyanide which are known to inhibit peroxidase activity. The system may be a parallel to the ascorbic acid - ascorbic oxidase and the cytochrome C - cytochrome oxidase systems in other plants, where a specific oxidase catalyses the initial changes of a series of reactions.

X-rays and Enzymes

IT has usually been thought that X- and γ-rays only influence enzymes when the dose is enormous, that cell division is inhibited by doses which have little or no destructive action on enzymes, and that, therefore, this inhibition is produced by a process in which enzymes play no important part. It has recently been found by W. M. Dale (*Biochem. J.*, 34, 1367; 1940) that purified carboxypeptidase and polyphenoloxidase in low concentration are indeed affected by radiation in small doses. The percentage inactivation of these enzymes is a function of the enzyme for a given dose of radiation. Absorption of a definite amount of radiation energy corresponds to a constant amount of enzyme inactivated. Inactivation of carboxypeptidase does not take place when the enzyme is acting on its substrate during irradiation, whereas the enzyme irradiated without its substrate is inactivated to 85 per cent. This, if it can be generalized, furnishes an explanation of the so-called delayed action of X-rays in the sense that the reserves of unused enzyme in the cell are inactivated by radiation, whereas that part of the enzyme already in action remains unaffected by radiation.

Structure of Multilayers

X-RAY and microscopic examinations of multilayers of some long-chain esters have been made by G. Knott, J. H. Schulman and A. F. Wells (*Proc. Roy. Soc.*, A, 176, 534–42; 1940). In order that microscopic examination could be made by transmitted light, the deposits were made on transparent bases such as celluloid, cellulose acetate, 'Perspex', 'Polystyrene', 'Formvar', vinyl acetates and other synthetic resins. Between crossed nicols, the individual crystals extinguished perfectly, showing that the molecules are arranged in some regular way from the base of the multilayer to the surface. The grain boundaries seen on the surface are therefore those of single crystals which have grown without interruption through the entire thickness of the multilayer. The same type of X-ray photograph was got from a stationary multilayer of ethyl stearate as from a single crystal of β-ethyl stearate rotated about the long axis of the cell. The 'spots' observed on oscillation photographs of multilayers of ethyl stearate taken in earlier work proved to be parts of circles, successive arcs of which appear on increasing the angle of incidence of the X-ray beam on the multilayer. It is concluded that the multilayers consist of microcrystals all oriented with a common axis normal to the surface. The single crystals were about 1,000 molecules thick in this investigation.

SOCIOLOGICAL ASPECTS OF EVACUATION

THE cross-section of our social life revealed in the stimulating and instructive report* of Mr. Geoffrey Shakespeare's committee on conditions in reception areas, does more than give a clear picture of the problems arising out of a sudden and extensive redistribution of the population and of the possibilities for good and ill innate in that process. It shows convincingly the way in which evacuation and education are linked with many other phases of our war-effort and with plans for reconstruction after the War. Again and again the efficiency of our war-effort in some particular field is powerfully affected by conditions in an apparently remote field. Adoption of many of the Committee's admirable suggestions is accordingly as much to be desired from the point of view of war-production or reconstruction as from that of educational or social welfare, and it is satisfactory to learn that most of them are being acted upon by the Ministry of Health.

A pertinent example is to be found in the matter of billeting. Much trouble is caused by the conflict between civilian and military billeting, and the report insists that there should be closer co-operation between all branches of the services and with the regional authorities. Periodical conferences between all billeting and quartering authorities and representatives of the Ministry of Labour are recommended. If the agreements reached are broken or points of dispute arise, the question should be referred for settlement by the regional commissioner and the senior military or air force officer in the region concerned.

It should not be forgotten, moreover, that this question of billeting impinges on that of man-power and production. The dispersal of factories on war-production, no less than the training of new labour and increasing the mobility of workers, particularly the skilled workers essential to the development of our full effort in production, will in itself make demands for billeting which must be co-ordinated with those arising out of evacuation, military or air force needs, if competiton and undesirable stresses and strains are not to occur. Furthermore, it may be necessary in some areas to exercise the Government's powers not merely to ensure that there is no evasion by well-to-do persons in the provision of billets, but also to see that unofficial and uncontrolled immigration into a reception area by those unable or unwilling to play their part in the national effort does not impede national and official schemes. Such instances may be rare, but failure to deal with them firmly can have far-reaching consequences.

An allied matter is the requisitioning of premises. Here, again, there is need for fuller co-operation. Adequate welfare arrangements depend on the availability of suitable premises, and while amenities for soldiers are very desirable, it is not right that all suitable premises should be so used to the detriment of evacuees. This, the report suggests, is not a matter always to be achieved locally, and to liberate premises for welfare purposes regular conferences between the regional commissioners and the service liaison officers are recommended. There are also complaints that many large houses have been earmarked by Government departments but are not being used, and a review of those not in use is also recommended. More drastic use of the powers of requisitioning by the Ministry of Health is recommended, particularly in regard to requisitioning of parts of occupied houses for welfare or other purposes, as well as fuller co-operation by educational authorities in the use of school premises for welfare purposes, both after school hours each day and during the week-ends.

The report displays an admirable grasp of all sides of the problem, and it emphasizes the importance of easing the burden of billeting in the reception areas, to secure which is one of the purposes of its recommendation for more drastic use of requisitioning powers by the Ministry of Health. More often than not, billeting officers have difficulty in placing new arrivals at once, and the provision of a larger number of buffer hostels is recommended for new arrivals as well as those who for any reason desire to change or should change their billet, and also to relieve the burden falling on householders. The desirability of such hostels is only one of many reasons why the best and fullest use should be made of all accommodation. The report visualizes the application of requisitioning powers in particular to parts of occupied houses, and even to stored furniture required for equipping homes or hostels.

There is, however, yet another way in which the growing demands for man-power and woman-power enhance the importance of the wisest use of available accommodation, and of the pooling of equipment, as well as accommodation, that are involved in this vast redistribution of the population. The increasing shortage of domestic labour and the insistent call for women to enter industry, as well as to leave their homes and join one of the auxiliary services of the forces or assist in the myriad activities organized by the Women's Voluntary Service, make it increasingly difficult for some housewives to respond to the demand for private billeting. The situations which will arise may well require careful handling if the development of our war effort is not to be impeded, or the door opened to what in war-time can only be described as evasion or malingering.

Much stress is laid in the report upon welfare. The provision of communal welfare services is regarded as the essence of success. Specific recommendations include the provision of mothers' clubs with communal feeding, nursery centres, arrangements for occupation for mothers, communal bath houses and laundry facilities, and week-end hostels where husbands can stay when visiting their wives. Attention to such matters has already proved a brilliant success in certain areas; but the execution of this policy involves the immediate appointment of a large number of welfare officers to encourage and supervise the formation of such facilities. In particular, the appointment of more welfare officers who understand the psychology of London mothers is required.

The provision of such welfare officers is probably one of the major difficulties. The report itself refers to a shortage of women of a suitable type for appointment as welfare officers, and with the simultaneous and growing demand from industry for welfare workers, largely stimulated by the Minister of Labour and National Service, it is difficult to see where the supply is to be obtained. Here, indeed, may be a matter in which the National Register might be utilized with advantage and a scheme of co-operation or control in making the appointments may well be essential, especially when it is remembered that welfare work is assuming increasing importance in the sphere of civil defence. The necessity for an examination and comb-out in the women's services if we are to make full use of trained personnel was well shown in the examples cited by Miss Ward in her speech in the debate on Production, Supply and Man-power in the House of Commons on January 21.

---

* Report on Conditions in Reception Areas. By a Committee under the Chairmanship of Mr. Geoffrey Shakespeare, M.P. Pp. 18. (London: H.M. Stationery Office, 1941). 3*d*. net.

Once again the report makes plain the inherent possibilities which may emerge from the complications caused by this redistribution of population, and its references to these possibilities are among the most interesting parts of the report. Country life is proving of the greatest value to the bodies and minds of town children, and it may be hoped that the new understanding of the country, and surprising interest in all rural pursuits may be shared by their parents sufficiently to help to secure a more balanced national economy. The new amenities and departures in social welfare now being established in the reception areas may have their own influence in arresting the drift from the country to the town if the nation can continue such experiments after the war.

If such hopes are to be realized, there must, indeed, be a fuller understanding by the countryman or woman and the townsman or woman of each other's sentiments, habits and outlook, the absence of which did much to wreck the evacuation scheme in 1939. While the Committee seems surprisingly satisfied with the success of the subsequent evacuation, it is clear that a large number of the evacuees have settled down happily in the reception areas, and that in the great majority of cases the experiment is succeeding, particularly with the unaccompanied children. The extent of the migration is sufficiently indicated by the 25 per cent increase in the population of the reception areas visited by the Committee during the first year of the War, exclusive of the large number of service personnel stationed in them, in contrast with a decline of more than 10 per cent in the year before the War. Two-thirds of this increase has been due to unorganized evacuation—the arrival, without notice, of more than a million people, many of the priority groups, who have since been billeted—and in the face of these figures the amount of confusion and friction, both of which are diminishing, is surprisingly small.

The mingling of town and country, the engendering of mutual understanding, of goodwill and good behaviour on both sides, encouraged as they have been by the ordeals of the last nine months, may well prove a solid asset when the need for evacuation is past. The suggestions and recommendations of the Committee, based on the experience gained, are designed to diminish the strains or friction set up and to promote fuller understanding as well as morale. They are not, indeed, novel. Many of the remedies have been frequently urged unofficially before—for example, in the reports of the evacuation committee of the Association of Architects, Surveyors and Technical Assistants, and of the Department of Social Science of the University of Liverpool.

Their official reiteration is none the less useful on that account, and has already had effect in regard to co-ordination in billeting and in the steps already taken to stop the dispatch of official parties to areas believed to be saturated, a position which has been reached already in certain districts more readily accessible from London.

The recommendations in regard to the immediate adaptation of emergency premises earmarked for the treatment of epidemics and the greater provision of premises for infectious diseases, for the wider extension of the district medical service and for the extension of the voluntary hospitals contributory scheme, where possible, to evacuees in the reception areas, are equally important. So, too, is the recommendation that careful watch should be kept on water-supply, sanitation and sewage disposal, where the influx of population has proved their inadequacy. Still more significant, however, is the reliance placed by the Committee on the regional machinery for giving effect to its recommendations. A wider use of regional powers originally, instead of giving large and drastic powers to the local authorities, which they were reluctant to use, might have avoided much unnecessary friction. The whole trend of the report in this respect is an answer to the severest criticism of evacuation contained in the Evacuation Survey report to the Fabian Society, edited by R. Padley and Margaret Cole, and it may well prove that adoption of the Committee's recommendations will give a further impulse to regionalism in Great Britain, and the handling of social problems on regional rather than local lines.

GRAVITY ANOMALIES AND THE EARTH'S FIGURE

THE literature on this subject is so voluminous and scattered, in many cases in periodicals that are not easily accessible, that a publication such as that by B. L. Gulatee*, which provides an introduction to the fundamental problems, with special reference to investigations developed in recent years and to practical applications, is likely to be welcomed by a wide circle of readers. Chapter i deals with the various gravity formulæ and gives brief proofs. The practical derivation of the empirical formulæ is reviewed in Chapter ii. Gravity observations and arc measurements show that a triaxial ellipsoid fits the geoid better than a spheroid; but it is pointed out that the ellipticity of the geoidal equator is not yet indisputably proved. The observations have been made only on limited portions of the globe, and until more gravity determinations are made in suitable areas the question will remain open.

Chapter iii gives an account of Clairaut's, Darwin's and de Sitter's theories of the figure of the earth. Certain objections are pointed out and reference is made to the more recent work of Jeffreys, in which he draws inferences from the moon's motion and so avoids the necessity of making any hypothesis about the internal state of the earth. In Chapter iv, which deals with gravity anomalies, a useful summary is given illustrating the application of such anomalies to the elucidation of the geological structure and history of those regions where they have been specially studied.

---

* Gravity Anomalies and the Figure of the Earth. By B. L. Gulatee. Pp. viii+116+10 figs. (Survey of India, Prof. Pap. 30, Dehra Dun, 1940.) R.3 or 5s. net.

No matter what hypothesis of compensation is adopted, considerable anomalies persist in certain regions, examples of which are Peninsular India, the Ferghana Basin, Japan, the Dutch East Indies, the Caucasus, the Caribbean Sea, many oceanic deeps and islands, and the African Rift Valleys.

Regions of large positive anomalies, being areas of overload, should be expected to be continuously sinking. A notable exception is provided by the island of Cyprus, which has risen, despite its positive anomalies. Such evidence, like that of the 'negative belt' around the Dutch East Indies, provides evidence of phenomena going on inside or below the earth's crust. Another application of gravity anomalies is the derivation of the form of the geoid; this is discussed in Chapter v. Finally, in Chapter vi, the various types of reference surfaces are defined and it is shown that it is necessary to distinguish a triangulation reference spheroid from one based on gravity measurements.

For convenience the diagrams have been placed all together at the end of the book on two double pages, so that they can be opened and seen clear of the text. A list of symbols is given for easy reference. If a second edition be called for, as seems likely, it might usefully be provided with an index.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Monday, March 3

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Dr. N. A. Mackintosh: "The Last Cruise of R.R.S. *Discovery II*".

Tuesday, March 4

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. H. A. R. Gibb: "Egypt".*

Thursday, March 6

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—General Meeting.

Saturday, March 8

GEOLOGISTS' ASSOCIATION (at the Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 3 p.m.—Annual General Meeting. Mr. W. P. D. Stebbing: "The Early Use of Subsoils in Farming, and the Farmer and his Instructors before William Smith".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

CHIEF ASSISTANT FOR HIGHER EDUCATION—The Director of Education, Town Hall, Bradford (endorsed 'Chief Assistant for Higher Education') (March 7).

LECTURER IN MECHANICAL ENGINEERING—The Principal, College of Technology and Commerce, Leicester (March 8).

HEADMASTER of the Sunderland Junior Technical School—The Director of Education, Education Offices, 15 John Street, Sunderland (March 10).

CIVIL ENGINEERING ASSISTANT to the River Ouse (Yorks.) Catchment Board—The Clerk to the River Ouse Catchment Board, 7 Langcliffe Avenue, Harrogate (endorsed 'Engineering Assistant') (March 10).

REGISTRAR of University College, Southampton—The Registrar, University College, Southampton (March 18).

HEAD OF THE SCHOOL OF TEXTILES—The Principal, College of Technology and Commerce, Leicester (March 24).

TENNENT PROFESSOR OF OPHTHALMOLOGY—The Acting Secretary of University Court, University, Glasgow (May 1).

GRADUATE IN ENGINEERING SUBJECTS—The Principal, Dursley Technical Institute, Dursley, Glos.

LECTURER IN THE MECHANICAL ENGINEERING DEPARTMENT—The Clerk to the Governors, Technical College, Chesterfield.

ASSISTANT ENGINEER for the Malayan Public Works Service—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M/9306).

SCIENCE, POLITICS AND GOVERNMENT

THE multitudinous ways in which science and its applications impinge on everyday life are apparent, as never before, to every thinking man. That it has required a major disaster in the form of a world war to bring about this realization is not to the credit of civilized people, but the fact should be faced that there is now widespread appreciation of the use—and misuse—which is being made of scientific knowledge. On the credit side must be placed the advances made in medical science as the result of the discovery of new treatments and new synthetic drugs, and the steps which are now being confidently taken to meet the nutritional needs of the nation in the absence of foodstuffs hitherto mainly imported from abroad, quite apart from the general rise in standard of living and increase of amenities to which we have grown accustomed in happier times. On the debit side there is the whole range of horror provided by modern warfare, based on scientific and engineering developments utilized for the destruction of man.

While this much will readily be conceded, there is not so general a concensus of opinion as to the part which science should take in the reconstruction and re-ordering of the world which will follow the end of the War. Correspondence which has been published in NATURE makes this point clear, and the differences of opinion are not only between scientific worker and layman but also among scientific workers themselves. One school of thought believes that science should be a discipline apart from worldly affairs, a disinterested pursuit of truth. Thus Prof. M. Polanyi has protested against a remark in an article in these columns to the effect that science can no longer be regarded as possessing "a peculiar holiness" setting it apart from other social interests. He has been answered by Dr. C. H. Waddington, who puts the case for utilizing scientific method over a wider field than that in which it now functions. Mr. R. H. F. Finlay has pointed to the success attained by chemical and engineering enterprises guided by scientific methods, and asks that science should take control in aspects of government in which it is competent. Dr. V. B. Wigglesworth interprets this as a suggestion that science should actually govern ; he asks if that would not be a definite threat to the freedom of scientific research, and states his belief that "the function of science in the national economy . . . is advisory". Elsewhere in this issue (pp. 298, 299), Dr. O. Blüh gives his views on reactions to planning in Central Europe during the past decade, and Dr. E. C. Childs points out some of the difficulties of applying experimental methods in this field.

This great diversity of opinion is evidence that the problem of the relation of science to society is still very much to the fore. It must be approached in a scientific manner ; in other words, the data should be gathered, deductions made and tested for consistency and when necessary scrapped, before action is taken. Admittedly, this is no easy task. Scientific men are but human, subject to prejudices like other men, though their training should enable them to recognize more readily when prejudice steps in and reason is put aside.

The fundamental point on which all can agree is that science represents the search for truth, for ever-increasing knowledge of the universe. It is inconceivable that this continuous probing of the secrets of Nature can ever be suppressed, even although circumstances may force it into the background for a while. In due time, some of the facts collected in this way come to have a direct influence on the lives of men, and in this way progressive civilization has been built up. We have now reached a stage when the contribution of science to everyday life has become a major one.

But in arriving at the present position, the conditions under which scientific research goes on have changed radically. The days of the natural philosopher pursuing his leisurely inquiries, perhaps alone, perhaps with one or two chosen disciples, have gone. Modern investigations are carried out for the most part in well-equipped laboratories attached to universities or large industrial concerns, while field-work often involves substantial expeditions. Although important discoveries are still made by the individual working with the minimum of apparatus, this method has become the exception. The tempo of research has increased and with this acceleration has come the team of investigators working together on different aspects of the same or allied problems.

Thus research has become to a large extent conditional on financial support, which has come in increasing amounts in recent years from State resources. As the fruits of scientific discovery in the long run lead to a higher standard of living and are of service to the nation as a whole, it is right that the State should contribute funds for this purpose; but this must not be allowed to endanger the freedom of the man of science to seek and to teach the truth. The administrative body can retain general control without allowing political, racial or religious views to influence the course of investigations or to falsify their results. The best method of exerting such control is still an open question, but it is fairly obvious that representative scientific bodies should take a prominent part. An experiment in this direction was the appointment last year of the Scientific Advisory Committee, which reports directly to the War Cabinet. This body, consisting of officers of the Royal Society and of the State research departments, is, of course, a war-time expedient, but it represents the kind of directing influence which should always be present in the Government, not only to formulate policy on the provision of funds for research, but, even more important, to deal with those numerous problems in which science impinges on human welfare both in war-time and in times of peace. Politicians may have special training and aptitude in the art of government, but they cannot be expected to appreciate in full measure the significance of scientific developments, or to foresee the course of events where the application of scientific knowledge is concerned. Here, then, science should have a place in the government of the country—not to deal with affairs of which it can claim no special knowledge, but with those in which it is particularly competent. It remains for the future to decide the precise manner in which science should be represented in the Government.

Closely entwined in the arguments for and against the participation of science in public affairs, are frequent references to the social responsibilities of science and scientific men. This theme has been discussed many times in these columns. In brief, it comes to this: the scientific worker must seek after truth, but he should not be saddled with the whole responsibility for the misuse often made of it by others. Nevertheless, he should, through his own organizations and individually, press for such appreciation of the true worth of science as would prevent its misuse. It may be argued that it is too much to expect to eliminate the individual, or the State, which would endeavour to exploit discoveries selfishly or without regard for the welfare of mankind, but at least the attempt would be worth while, and it would bring nearer the day when such an individual or State would be outlawed by mankind.

It is perhaps in this wider field of international affairs, paradoxically enough, that the influence of science has produced its most tangible effect. As Prof. A. V. Hill showed in his recent address to the Parliamentary and Scientific Committee (see NATURE, March 1, p. 250), international congresses for the discussion of progress in various fields of scientific endeavour have been effective instruments in promoting progress and understanding. Further, as has frequently been emphasized in these columns, the achievements of the scientific and technical services of the League of Nations have marked a noteworthy stage in international collaboration.

Scientific men, working in their own fields, have given a wide significance to the phrase 'science and society'. They have shown that they can rise above political considerations in affairs of the State and internationally, to the lasting benefit of humanity. 'Science' has, indeed, become inseparable from 'society'; one is dependent on the other. On the part which is played by science—using the word in its widest sense and including the inquiring and unprejudiced approach which should be characteristic of scientific investigation—in determining world conditions after the end of the War will depend the stability of international affairs by which alone civilization can flourish.

INTERNATIONAL CULTURAL RELATIONSHIPS

THE concentration which all the sources of publicity during a period of crisis must give to the War tends to diminish proper and adequate comment upon other activities within the country. It may be for this reason that but little notice has been taken of a remarkable document entitled "Greece No. 1 (1941) Convention between His Majesty in respect of the United Kingdom and His Majesty the King of the Hellenes respecting the Relations of Learning and Culture between Great Britain and Greece"*. Yet this Treaty should not go unregarded, for it marks a notable development in British relationships with foreign countries. It is a Treaty not of war and peace, nor of commercial bargaining; it is uncontaminated with the breath of propaganda; it is an attempt in an honest and unequivocal way to develop the relationships of thought and mind, of literature and science, between two great civilized peoples.

There is a dramatic propriety in the fact that the first Treaty of this kind to which Great Britain has given her signature should be with Greece. The contact of British civilization with that of Greece extends for centuries, and the basis of much of British education has been upon the classical language of that country; while from a more immediate consideration, in this hour when the face of history is being changed, Greece has been an ally that has shown that the forces of totalitarianism can be faced by resolute mind and an equal resolution in arms. Behind this document there is further a certain atmosphere of tragedy, for the signature with which it concludes is that of General Metaxas, a great friend of Great Britain, and one who had always encouraged British cultural institutions as they developed in Grecian territory. Further, though his signature nowhere appears, it is common knowledge that on the British side the initiative for this cultural bond came from that dynamic personality, Lord Lloyd, who, through the British Council, was transforming the cultural relationship of Great Britain with foreign countries.

The articles of this Treaty are modest enough. Cultural institutions in the two countries are to be given all proper encouragement and possibility for development. Students and professors and men of learning are to be welcomed equally in London and in Athens. Further, an attempt is being made to ease the entanglement of university regulations which have hampered the passage of students from one country to another and made less easy that fraternity of scholarship which existed in the Middle Ages. Above all, the British traffic of the mind in books and periodicals is to be promoted with as little impediment from customs duties, import quotas and other "relevant regulations" and all such taxes upon knowledge as may be possible.

It is particularly welcome that this Treaty of culture is not confined to any single branch of learning, but that science is to be encouraged along with art and letters. The British Council has already anticipated the action proposed by the Treaty in bringing to Great Britain a number of young Greeks, some of whom are still in British universities, and among them there are young men of science whose work has been reported as reaching a high level of distinction. Nor are the signs lacking that the British Council fully realizes that its definition of culture must include British achievements in medicine and engineering and the pure sciences, and that in due course it must organize the best of expert opinion in Great Britain to break down any intellectual insularity that may still remain. The Treaty belongs to the things which are permanent and will not only survive the War but will also become more active and real once this conflict is over. We live to-day in the sullied atmosphere of propaganda, and it may be that under the conditions of modern warfare that is inevitable; but when peace comes it is through instruments such as this cultural treaty with Greece that British contact with foreign countries should be based.

The pressure of war allows but little leisure for tributes to be paid to the dead, and the individual is likely soon to be forgotten in the major stress of events. In the few pages of this convention there remains a tribute to Lord Lloyd which should encourage those who are engaged upon the work of the British Council to increase their endeavours, and should make Great Britain affirm that in the future it will carry the best that its learning, both in the sciences and in the humanities, can give to all free peoples who may welcome such a proper and uncontaminating contact.

A ZOOLOGY FOR STUDENTS

A Text-Book of Zoology
By the late Prof. T. Jeffery Parker and the late Prof. William A. Haswell. Sixth edition. Vol. 2. Revised by Dr. C. Forster-Cooper. Pp. xxiii+758. (London: Macmillan and Co., Ltd., 1940.) 36*s.* net.

WE can now welcome the appearance of volume 2 of the new "Parker and Haswell" (volume 1 was reviewed in NATURE of October 5). It is the volume dealing with the Chordata, a phylum in which important advances in our knowledge of both fact and theory have been made and needed incorporation to bring it up to date. Its format, like its companion volume, is larger than that of the previous five editions, the last of which was published in 1930, and the type is slightly larger. The pages number 758 as against 683 of the previous edition. More space has also been gained by the omission of the two general chapters on distribution and philosophy. Older readers will perhaps regret the loss of these, but, however much they might have desired their retention, it is fair to say they only represented a résumé of our knowledge on these topics forty-three years ago. It is justly pointed out in the preface that to have brought them up to date would have involved their expansion, and consequent enlargement of the volume beyond reasonable bounds. The space thus gained has been used for the incorporation of a very considerable amount of recent information.

It must not be thought that this edition is simply the last with additions; it is reorganized, largely re-written, and to a considerable extent re-illustrated: it is in effect a *new* edition and not simply a revision. A large number of the old illustrations have been excluded and new ones, including some excellent photographs, added, and of these about thirty appear to be published here for the first time. Although they are fewer in number (656 as against 1,169) they actually form a more useful collection, and the standard of reproduction is throughout excellent. Perhaps the most serious criticism regarding the illustrations is the retention on p. 350 of Wiedersheim's very diagrammatic and not accurate representation of the venous system of Salamandra when more precise information is available. Three diagrams of the suggested phylogenies of the fishes, the reptiles and the mammals plotted against the geological periods as a time-scale form useful additions, as many students gain a clearer idea from such schemes than they do from any amount of straightforward text.

The text-figure legends are fairly uniform and unusually commence with the scientific name in black face type unless the subject requires other treatment. The same consistency has not been maintained with regard to nomenclature, and it is rather curious that well-known names have been rejected, correctly, of course, in some instances, whereas in others they have been retained. Thus, to take a few examples, Bdellostoma becomes Eptatretus, Scyllium becomes Scylliorhinus, Echidna becomes Tachyglossus, Galeopithecus becomes Cynocephalus; but, while Ceratodus becomes Epiceratodus in the heading of the section, it remains Ceratodus in the text. On the other hand, Branchiostoma remains Amphioxus, *Lampetra fluviatilis* remains Petromyzon and *Oryctolagus cuniculus* remains Lepus. While on the subject of names, the diagram on p. 188, in which a spine is clearly indicated on the anterior margin of the anterior dorsal fin, is surely that of Squalus, although it is labelled Brachælurus. This question of correct naming is important in a students' text-book, for any incorrect names that are acquired in early years are liable to persist in an amazing way: it is just as easy for the beginner to learn the right name. In line four from the bottom of p. 460 Neornithes should read Neognathæ. On p. 639 it is stated that the mammary glands are modified "sebaceous glands": why not say sweat glands, since that has been established beyond reasonable doubt by various workers, and the mode of producing secretion differs fundamentally in the sweat and sebaceous glands?

In correspondence with the unequal rate of advance in our knowledge of the fundamental facts in different groups, varying amounts of revision have been necessary in dealing with the different classes of the Chordata. Least alteration is noticeable in the Hemichorda, Urochorda, Amphibia and Aves. The sub-phylum Agnatha, the Pisces, Reptilia and Mammalia on the other hand, have been far more drastically treated, and it may be said at once that this is a much needed improvement. In the first three in particular considerable stress has been laid on the palæontology of the groups. Some knowledge of the palæontology is, of course, essential to the understanding of the relationships of the living groups, since they are but the end twigs of a tree the main branches and trunk of which can only be revealed by this method of approach. On the other hand, it is true that many students of zoology unfortunately have no knowledge of geology, and they can never hope to see many of the types dealt with, or, if they did see them, they would be quite unable to interpret them. It is in the groups that they have been most critically re-written that palæontology has made the most conspicuous contribution to our knowledge, and it is fortunate that the revision has been made by an acknowledged master in that field. The volume is furnished with an exceptionally full index.

Here then we have the completion of the new "Parker and Haswell" arisen Phœnix-like out of the ashes of its former self, the good features remaining, but embellished and burnished by its ordeal of fire. Such a thorough revision has long been needed, and it has been carried out in a most praiseworthy manner. Students for some time to come will have reason to thank both the revisers of the volumes and the publishers for once again firmly securing "Parker and Haswell" on its pedestal as the most useful text-book of its size and compass in the English language. It is a pity that the price is so high, each volume costing as much as the two volumes did in the original edition, but for that the publishers are not to blame. It is due to causes not under their control, and, compared with other advanced text-books, it is certainly good value for the money.

C. H. O'DONOGHUE.

A HISTORY OF MYCOLOGY

The Advance of the Fungi
By E. C. Large. Pp. 488 + 6 plates. (London: Jonathan Cape, Ltd., 1940.) 18*s*. net.

THIS very interesting book is a history of research on plant diseases, especially those due to fungi. It is written in the new style, in which the events of the history of science are related to their social background, and it contains much fascinating material.

The author begins with an account of the potato murrain. Its appearance in England was noted in August 1845, and at once received the attention of the leading botanists, including Dr. John Lindley and the Rev. M. J. Berkeley. Within a few weeks, news of the spread of the disease came from Poland, Germany, Belgium and France, and from nearly all parts of England.

There had been a peculiar change in weather during the summer. The early period had been fine, with temperature above the average, and had then been suddenly followed by three weeks of exceptionally damp and cold weather. Many botanists, with Lindley at their head, believed that the bad weather caused the plants to be overladen with water. This produced a sort of dropsy, and putrefaction. Berkeley, on the other hand, was impressed by the mould observable on the diseased plants, and suggested that it was the cause and not the consequence of the disease.

This raised once more the conception of the nature of disease in general. Were diseases intangible entities or were they due to concrete causes that could be seen and controlled? It is notable that Berkeley, the Christian clergyman, was the most resolute in the rejection of all nebulous and transcendental explanations of disease, while the more materialistically minded men of science were the most eager to espouse them.

This wonderful man was of commanding presence and robust physique. He was educated at Rugby and Cambridge. He was a perpetual curate, and maintained a large family on a very small stipend. He had to take in pupils to increase his means, and he was active in his parish. He was a good classical scholar, and read all the proofs of the "Genera Plantarum" by Bentham and Hooker. He was the leading authority in England from 1836 until 1870 on fungi. He collected a herbarium of ten thousand species of fungi, which was ultimately acquired by Kew, and he described nearly six thousand new species. Finally, he retired on a minute civil pension.

While the potato murrain was stimulating researches that helped to transform the conceptions of plant disease, and consequently of human disease, it was an instrument in profound political changes. Sir Robert Peel was seeking plausible reasons at the time for the repeal of the Corn Laws. The murrain attacked the Irish potato crop and destroyed the food of a large section of the Irish population, and Peel found in this event most moving arguments for free imports of corn. Thus the potato murrain was a trigger which released Britain on her career of free trade in the nineteenth century. Some details collected by the contemporary *Times* reveal the conditions of the Irish labourers. The annual wages were about £3 18*s*. A pig worth about £4 was reared, making an annual monetary income of about £7 18*s*. From this, about £5 rent was paid, leaving £2 18*s.* to buy meal, clothing, tools, candles, medicine and drink for the year. The food consisted almost entirely of home-grown potatoes, each person eating from eight to fourteen pounds per day.

The fungi of the potato murrain advanced with vengeance on the Irish population. Relief measures became imperative, but they were conducted with a meanness that has left a scar. Are we not now having to pay for such errors ?

Among the many interesting sections are accounts of the researches of the Tulasnes, Tillet, and de Bary. The Tulasnes were devout Catholics who made wonderful drawings of fungi in order to reveal the beauty and infinitude of the Creation. Their researches were dedicated to the glory of God, and in their zeal they sometimes saw things that did not exist ; but this was trivial compared with the discoveries they did make. The metamorphoses of the fungi were very complex, and their obstinate belief in the subtlety of Nature liberated the imagination of the men of science, and assisted them to discover the almost incredible series of changes.

Tillet's brilliant researches in 1751 on bunt in wheat, with his one hundred and twenty adjacent plots containing differently treated seed, so that the results on each could be compared, are described ; and the exact researches of the acute and intelligent twenty-two-year old de Bary in 1853.

The later sections of the book on such subjects as chemical fungicides are not less interesting.

There is one subject, however, in which the author is perhaps a little unfair. He writes hard words about Lyon Playfair, who was consulted on the problem of the potato murrain in Ireland, and gave advice that was of little scientific value. He was a chemist, and did not know much about fungi, and he was also a free-trade individualist particularly anxious that the relief for the starving Irish should not undermine the individualistic strand in their moral fibre.

Playfair's performance on this occasion was not one of his happiest ; but in other directions he gave the most signal service to science. The success of the Exhibition of 1851 and the fruits of the scientific institutions founded with its profits are largely due to him, and his combination of scientific knowledge with political skill was, on the whole, of great value. He was one of those rare statesmen of science who could coax, wheedle or bully governments into making more use of science, and more of his type would be very useful to-day. J. G. CROWTHER.

TEACHING PHYSICS

The Demonstration Laboratory of Physics at the University of Chicago

By Prof. Harvey B. Lemon and Fitz-Hugh Marshall. Pp. iv+127. (Chicago : University of Chicago Press ; London : Cambridge University Press, 1939.) 9*s.* net.

THE reactions of scientific workers to war are in one respect like those of all normal men. Self-preservation comes first ; after that, some can think only of bigger and better destruction. A book dealing with so constructive a process as education in the physics laboratory can have little present interest for them. However, for those who both turn and escape from destruction to construction, the book has a very special interest.

Teaching physics is a new subject. When J. J. Thomson first began in the early 'seventies, there were only six physics laboratories in England. Now there are more than three hundred. Their rapid growth has been haphazard. Courses in practical physics were planned to train students both to use physical apparatus and to understand theoretical physics. The dual purpose of using practical physics to train both hands and head has resulted in a tradition in the universities that each student must spend many hours each week in the physics laboratory. To what extent this is necessary is doubtful. Workshop and glass-blowing bench give better hand training. Practical physics of the teaching laboratory is an inefficient way of training hands. For students who follow instructions as if they were cookery recipes, it is no better trainer of the head. In the Ryerson Demonstration Laboratory of Physics at the University of Chicago, Prof. H. B. Lemon and Dr. F.-H. Marshall have broken with tradition by providing, in effect, the maximum training of the head with the minimum of hand. About 240 experiments covering all the main phenomena of physics from inertia to X-rays and cosmic rays are completely set up in more or less permanent form so that they 'work' without fail or fake.

The laboratory started as a physics museum for showing physical phenomena rather than historical apparatus. The equivalent in Great Britain is in that small part of the Science Museum exhibits at South Kensington to be found, oddly enough, in the children's section in the basement. Plans, very clear photographs and notes enable the physicist easily to visualize the Chicago laboratory. The authors give also a thorough discussion of its different uses. Over a period of seven years about 40,000 students and visitors have seen and used the experiments as part of introductory general courses or 'surveys', as preparation for the equivalent of the Intermediate B.Sc. and 1st M.B. courses, or as part of the training of teachers. Public 'open evenings' have also enabled citizens of the community around the University to observe physical phenomena directly instead of merely reading about the rather mysterious physical universes presented to them, with or without alleged theological implications, in popular science literature.

While the demonstration laboratory gives the student little practice in laboratory techniques, it must be remembered that the majority of those studying physics in a university never become physicists. There can be little doubt that developments as striking as those of biochemistry will be made wherever two sciences overlap. A biophysicist, for example, will have to know all the main phenomena of physics, chemistry, botany and zoology. The demonstration laboratory would help in acquiring the knowledge quicker than would the ordinary practical laboratory, and the time saved could be spent upon mathematics and upon the specialized laboratory techniques actually needed for future use.

This volume can therefore be very strongly recommended to the attention of all concerned with teaching any of the sciences. To the reviewer it carries deeper significance. The object of the laboratory to which it directs attention is "first-hand contact with the phenomenological source material of the science", that is, with observable facts. These are the only things in which agreement between human beings has ever, so far, been reached. While the men of action are urging mankind on in a struggle for *unobservables*, values and the like, the ineffectual intellectual may well wonder if the ideas behind the Chicago demonstration laboratory—the stressing of *observables* in which men agree—may not lead to greater human happiness.

W. H. GEORGE.

METHANE AS A FUEL

Methane
Its Production and Utilization. By Dr. J. P. Lawrie. Pp. 66. (London: Chapman and Hall, Ltd., 1940.) 6*s*. net.

AT the present time there is very little natural petroleum in Great Britain, and the country is almost entirely dependent upon imports for supplies of fuel oil and petrol. In this book Dr. J. P. Lawrie has shown that there are available substantial quantities of methane gas which, if used as an alternative to petrol, could replace a large proportion of the fuel at present being imported.

Methane occurs in coal deposits, and is released as fire-damp when the pressure of overlying deposits is eased during mining operations. While there are no actual figures obtainable of supplies of gas available from the blow-holes of mines, Dr. Lawrie instances two mines which produce 10,000,000 and 1,000,000 cubic feet of methane per day. As there are 1,250 collieries in Great Britain, there is no doubt that the total quantity of gas available from this source is substantial. At the present time all the methane from mine blow-holes is wasted, and while private enterprise is aware to some extent of the value of these supplies, little can be achieved until a survey is made by an official body.

Methane is also found associated with oil, and the recent search for petroleum in Great Britain has indicated that supplies of the gas are available from this source. For example, in Scotland there is a site from which 12,000,000 cubic feet of practically pure methane can be obtained per day. Quantities have also been revealed in borings in Derbyshire, Sussex, Yorkshire, and Lancashire.

Apart from these natural occurrences, methane can be obtained from the treatment of coal, from ordinary coal gas as supplied for towns' use, coke-oven and water gas. Production from these sources, however, involves the utilization of an existing fuel. Thus, in relieving the demand for petrol by the manufacture of gas, either an indigenous or an imported fuel is being consumed. In war-time, particularly, the relieving of one shortage might merely have the effect of causing another. There is, however, another source not falling within this category, and that is sewage. Dr. Lawrie is of the opinion that the production of methane by the digestion of sewage sludge offers the most satisfactory source, apart from supplies from natural sources. Summarily, he calculates that quantities of methane from all known sources can supply not less than 7 per cent of the country's peace-time requirements of fuel substituting petrol.

FOUNDATIONS OF TROPICAL AGRICULTURE

By Prof. C. W. Wardlaw,

University of Manchester (formerly of the Imperial College of Tropical Agriculture)

> "'You must certainly have a vast estate,' said Candide to the Turk.
>
> "'I have no more than twenty acres of ground,' said he, 'the whole of which I cultivate myself with the help of my children; and by our labour we avoid three great evils, idleness, vice and want.'
>
> "'Elevated stations,' said Pangloss, 'are very dangerous, according to the testimonies of almost all philosophies.'
>
> "'I know,' said Candide, 'WE MUST CULTIVATE OUR GARDEN.'"
>
> Voltaire.

Imperial College of Tropical Agriculture, Trinidad

Via cilendi haud facilis

The Imperial College of Tropical Agriculture in Trinidad was founded as the West Indian Agricultural College in 1921; to provide instruction in tropical agriculture and in the cultivation and preparation for market of tropical produce of every kind, and also to continue the work of the Imperial Department of Agriculture for the West Indies. In 1924 the name was changed to "The Imperial College of Tropical Agriculture". Two years later the College was incorporated by Royal Charter, and in the following year it received the patronage of M.H. the King. It is now the recognized centre for post-graduate training in tropical agriculture for the agricultural services of the Colonial Empire.

The Oldest Industry

As an institution for teaching and research the Imperial College of Tropical Agriculture is still in its first youth. Yet its roots are deep, for it has assimilated to itself the oldest and most honourable traditions in the world: man's need to till the soil and make it bring forth abundantly.

The way of the cultivator is hard. In the realm of agriculture man enjoys at best but a qualified success. In the Middle Ages, when famines and plagues periodically swept the face of whole continents, the heart-breaking vicissitudes of agriculture were recognized and passively accepted as being something in the nature of things, to be tolerated with patience and fortitude. To-day we still recognize the endless complexities and difficulties of agriculture, but our mood is no longer one of submission: we know that its problems, be they ever so complex, are not insoluble. With the passage of time science, in her many forms and even in her youngest branches, has been recruited to the aid of the oldest industry; over the whole world agricultural industries are being succoured and assisted as never before. Resignation in the face of famines, plagues and kindred agrarian mishaps, is no longer conceivable. The combination of the methods of science with the age-old art of the cultivator constitutes a new and unprecedented phase in human endeavour, and we strive with the heartening assurance that in spite of all difficulties we shall yet venture through adversity to success.

From Cancer to Capricorn

The citizens of medieval Europe who used spices from the distant Orient to preserve and give flavour to their food, and knew something of the strange exotic merchandise that came by caravan and quinquereme from the vast and little-known world beyond the Mediterranean basin, were yet entirely unaware of the enormous wealth that remained—and, be it said, to this day still remains—to be exploited in the tropical belt. That a swamp reed with a sweetish sap would one day be the basis of a major industry the world over; that bananas, in whose shade wise men of the East sat in pious contemplation, would give rise to a marvellous industry in the New World; that citrus fruits from the Orient would find their way to all lands where the hot sun beats down; and that the many new plants, maize, potatoes, tobacco, to mention only a few discovered by the Conquistadores in the New World, would become infinitely valuable sources of food in the Old: all these, and a hundred others, of the wonderful possibilities that lay untouched between the bounds of Cancer and Capricorn, were unknown to our medieval ancestors, yet but awaited the day when men would set out in search of new lands, to bring back undreamed-of spoil.

More often than not the gold that the Conquistadores sought with such incredible energy and ferocity failed to materialize. Nor, with some rare exceptions, did they realize that the real and enduring value of their discoveries and conquests lay, not in mines, but in those vast tracts of rich agricultural territory found by them in that equatorial belt which imaginative geographers have described as the Torrid Zone. Here, indeed, in the

Fig. 1.
IMPERIAL COLLEGE OF TROPICAL AGRICULTURE: MAIN BUILDING.

newly found realm of tropical agriculture, was wealth personified, a veritable El Dorado for the unnumbered generations that would come after.

RAISON D'ETRE

From Cancer to Capricorn, whether deluged by tropic rain, or starved for water, lies a vast area of which the potential productiveness of the food and commodities that men require has scarcely begun to be realized. But already, because mankind tends to blunder on its myopic way by a process of trial and error, there is much in the sphere of tropical agriculture that is faulty, wasteful and inefficient, and which represents an abuse both of opportunity and material—this in an industry the welfare of which is of fundamental importance to all. For posterity as for our own generation, for all the many peoples scattered over the face of the earth, it is now recognized that the vast resources of the tropics should be treated in no haphazard fashion but should be afforded all the advantages of the accumulated knowledge of agriculture, the steadying guidance of an enlightened administration, and the unstinted assistance of science. To this end the Imperial College of Tropical Agriculture was founded, that its students should go forth to disseminate a new knowledge and idealism to the farthest ends of our great Colonial Empire.

AMENITY

For those to whom the tropic urge has proved irresistible it would indeed be difficult to begin a career in circumstances more favourable than those provided at the Imperial College of Tropical Agriculture. A green and pleasant land, Trinidad provides good living conditions, ample scope for recreation, a wide variety of interests, and, not least, a friendly and kindly people whose hospitality is unstinted. If a man be at all adaptable, he can find in Trinidad most of the things that make for happiness and a sense of life well lived. There must, indeed, be few places in the tropics of which as much can be said.

Although it is now more than four hundred years since the first European visitors went to the shores of an island which the aboriginals called Iere—the 'Land of the Humming Bird'—Trinidad is still unspoilt, and for those willing to explore, is a land of adventure and romance. From coast to coast a marvellous profusion of vegetation greets the eye; untouched virgin forests still brood with the solemnity of a thousand years, and the vast gleaming swamps are bright with the plumage of wild fowl. Tucked away in a fold of her green mantle, Trinidad hugs to herself one of the wonders of the world—the Pitch Lake where Sir Walter Ralegh once caulked his ships. Which thought almost tempts us into the byways of digression, for Trinidad possesses a background of remarkable

Fig. 2.
IMPERIAL COLLEGE OF TROPICAL AGRICULTURE: FARM BUILDINGS.

historic interest. Conquistadores were there in olden days, in search of El Dorado, and, in the murky waters of the Orinoco that lave her shores, many hard-fought naval engagements took place. As to her peoples, the island has become the adopted home of many nationalities, and life is colourful and interesting in proportion.

And so we come to the College.

Almost like a university with its atmosphere of detached calm, the College buildings, solid, dignified and with a sense of spacious repose, are set on an expansive savannah, a green pasture, kept trim and orderly, to which shapely angeline and saman trees lend an impression of coolness and grace. Round the savannah are various red-roofed laboratories, students' hostels and staff houses, while beyond, the eye rises to a densely wooded mountain-side cleft by deep valleys, with a Benedictine monastery perched in high seclusion.

DIDACTIC

The young men destined for the Colonial Agricultural Service are selected with great care from home and dominion universities and from agricultural colleges. As a rule they have already taken an honours degree in science or agriculture, but personality, social qualifications and physique are also considered essential for a service that is as exacting as it is many-sided.

After a year at the Cambridge School of Agriculture, the cadets proceed to Trinidad for a final year of studentship, which initiates them into a great service—the Colonial Agricultural Service. For most of them it must indeed be a wonderful year. The glamour of the tropics, the strange and varied experience of living in a new country peopled with many races, and, not least, the feeling that they are at length coming to grips with their life-work.

The principal function of the College is the instruction of students in tropical agriculture and methods of research relevant to modern agricultural requirements. Accordingly, a closely knit course has been built up over the years whereby the student is given a thorough insight into, or, if he is not a specialist, a good working knowledge of the several sciences which play the part of handmaiden to that vast, comprehensive whole—agriculture.

A knowledge of tropical soils—which are not always as good as the untravelled layman has been led to suppose—is, of course, fundamental. Soils make a whole universe. The problems of their formation, utilization, deterioration and regeneration under the many and varied types of climate and systems of cultivation found between Cancer and Capricorn, the methods of measuring their actual or potential fertility, and of studying the lives of the micro-organisms which inhabit them, are all made the subject not only of discourses in the lecture room, but also of demonstration and experimentation in the field and laboratory.

From the good earth spring the tropical crops—a grand and goodly host of them the variety and abundance of which far exceed the common knowledge of those who have never stirred beyond the confines of temperate lands. So, in his agricultural classes, and with the help of a living museum on the College Farm and in the island as a whole, the student becomes acquainted with the vast array of vegetable commodities that can be produced throughout the equatorial belt: rice, pulses, maize, among cereals; sugar cane, cotton, tobacco, cocoa, coffee, spices, rubber, bananas and exotic fruits innumerable, oil, fodder, and fibre crops, to mention only a few of the economic plants with which he may have to deal later in his career. But that is only part of the agricultural course. The study of livestock, its care and improvement in the tropics, the use of implemental tillage adapted to different needs and conditions, the methods of field experimentation, and many other aspects of knowledge and practice, all find their place in the curriculum.

As well as being marvellously and variously productive of the goods that man requires, Nature, in her infinite variety, has also at her command the forces of dissolution and decay. Diseases and pests emerge unheralded from the unknown to claim a heavy toll in the domain of agriculture. So in preparation for the maladies which will inevitably beset his crops wherever he goes, the student's education includes a survey of fungal diseases and insect pests and the methods by which they can be combated.

Faced with the large assemblage of tropical crops more or less completely new to him, the student, already a botanist, perforce must continue his botanical studies, not merely to familiarize himself with their structure, habitat and mode of life and the influence which different environments exert on their cropping power, but also to consider to what extent, by breeding and selection, new types, more productive, more disease-resistant and more adaptable to different environments can be obtained. Here it may be noted that the College course is so arranged that soil, agricultural, botanical and pathological studies, as well as field demonstrations, are carried out crop by crop in the closest conjunction.

Not last or least, there is instruction in the science of economics, for agriculture, as well as being an art and a science, is also a business. So is there a need for instruction in the methods of economics as applied to agriculture in order that the true sources of wealth may be adequately understood, wasteful methods eliminated, and the financial and administrative fabric so adjusted as to make for increasing improvement, not only in the mere matter of pelf, but also in respect of the wider aspects, internal and external, of the social well-being of the community.

From this brief and rapid survey some impression may be gained of the wealth of new knowledge and experience that awaits the agricultural cadet. Nor is that all. He also receives instruction in veterinary science, and being himself an animal liable to the ills that beset the empire builder in torrid climes, is duly instructed in the niceties of tropical sanitation and hygiene.

So, at length, after a year that must seem all too short, the student stands forth, as yet inexperienced—a defect which time will rectify—but clad in the armour of knowledge, the torch of science in his hand, ready for service and determined "To strive, to seek, to find and not to yield."

Perhaps, if you travel the world and penetrate into strange and remote places, you may meet old College students. They are to be encountered everywhere throughout the Colonial Empire and Mandated Territories, in East and West Africa, Malaya, New Guinea, the Solomon Islands, British Guiana, the West Indies, Palestine, the Sudan; and they are doing splendid work. This aspect of British Imperial service must be the envy of the world. For while other countries may also possess fine colonies, none, without exception, can boast of such a service, unified by the fellowship that comes from the system of training and the fact that they have one and all studied in the same College. Indeed, the bonds that unite past students not only among themselves but also to their former professors at the College, has through the years created a system of correlated endeavour seldom to be encountered.

DIPLOMATES

In its attempt to provide men for the agricultural services, official or commercial, the College casts a wide net. With the passage of time a diploma course has been evolved for the instruction of students of school-leaving age who are not proceeding to a university but who desire to qualify for a career in agriculture. These students receive a well-balanced training in the sciences pertaining to agriculture, in the many aspects of agriculture itself, and, if they wish to specialize in that subject, in sugar technology. For the latter purpose there is attached, to the College a model sugar factory, where a thorough training in all matters relevant to the production and preparation of that goodly commodity may be obtained. The members of the diploma course are derived principally from the West Indian islands and British Guiana; but they are also occasionally recruited from regions considerably more remote, while periodic accessions from the French West Indian Colonies and from the Latin American Republics provide a pleasing note of cosmopolitan variety to the College scene.

Diplomates may also play an important part in promoting the welfare of tropical agriculture. They are eligible for appointments in West Indian departments of agriculture, they do important work as sugar technologists, and are recruited as managers or advisers to some of the larger estates.

LIBRARY

The literature of agriculture, extensive and varied as its theme, cannot be adequately treated in a few words. But suffice it to say that in the College Library there has been assembled not only a comprehensive and representative collection of books, but also a wealth of information in the form of bulletins and memoirs, pamphlets and periodicals, from all parts of the world. Even in the world of letters modern conditions call for speed and efficiency; to meet this need the Library has been indexed and catalogued on a system whereby the information available on any subject can be immediately obtained.

THE SCIENTIFIC WAY

If the way of the agriculturist is hard, he no longer stands alone. In the attempt to control the wayward forces of Nature, the resources of modern science are daily being applied on an increasingly extended front—a campaign in which the Imperial College plays its part, for by its constitution it is an institution for the promotion of research as well as for the propagation of knowledge. Because its functions are imperial, and its work intended to provide information for agricultural officers in their many spheres of activity, the major investigations undertaken fall into that category which may perhaps best be described as 'fundamental applied research'; but local problems are also tackled in collaboration with West Indian Departments of Agriculture.

Of necessity, the crops grown in the West Indies provide the raw material for investigation; but the problems selected for study are such as will tend to elucidate basic scientific principles rather than to yield results of immediate practical importance but of limited application. Not infrequently the research projects call for the collaboration of specialists in different fields. To illustrate a single instance of a College team in action and of the way in which investigators throughout the Empire become linked together in a common cause, reference may be made to banana research. Some twelve years ago the heavy losses resulting from the rapid spread of Panama disease—a soil-borne disease of great severity widely distributed throughout the tropics and affecting the Gros Michel banana, the principal variety of commerce—gave rise to a scheme requiring the services of a pathologist to study the malady under field conditions, of a plant breeder whose task was to produce commercial hybrids resistant to the disease, and of a physiologist to investigate the cold storage and ripening behaviour of resistant varieties or hybrids which might be used as commercial substitutes for the Gros Michel. These three sub-divisions of the research programme were centralized at the Imperial College, and among other things led to the construction of plant quarantine houses and of a Low Temperature Research Station. But only part of the story has been told. To search for resistant varieties which might serve as substitutes for the Gros Michel and to provide materials from which desirable hybrids might be obtained, collectors from the Royal Botanic Gardens at Kew were sent to the East, the original home of the banana. In this unusual quest, which still continues, forestry and agricultural officers in remote places have taken a not inconsiderable part. Further, in order that diseases which have attained to epidemic proportions in the Orient might not be introduced into the West Indies, it was necessary to prepare a special quarantine house at Kew and one in Trinidad to provide the necessary safeguards. Meanwhile, in Trinidad, with the passage of time, new and promising hybrids have been raised and their carrying qualities tested, and a vast amount of useful information has been obtained and published on the botany of this important genus, the behaviour of different varieties and hybrids in storage, the basic physiological processes involved, and on the host of diseases which are liable to cause losses in the field and wastage during transport and ripening. By such a combination of effort it is evident that not only are present needs being served, but also a sure foundation of knowledge is being laid down for the future.

The fascinating story of banana investigations is only one illustration of the many research projects now receiving attention at the College. Reference might equally have been made to work on such crops as cacao, citrus, sugar cane ; to storage investigations on exotic fruits ; to soil surveys and kindred earthy topics ; to economic probings into the workings of tropical industries and social systems ; and to the many and varied problems of entomology and mycology. Lastly, it may be noted, a special point is made of introducing students to these manifold activities ; as a result they go forth, not only with some knowledge of the methods by which problems may be tackled, but also with the feeling that they have, to some extent, become personally identified with researches whose value will become increasingly evident with the passage of time.

In a free world the fruits of knowledge should be available to all. This ideal pervades the work of the Imperial College of Tropical Agriculture. The results of all investigations are published in appropriate journals, and scholarly contacts are maintained with research workers throughout the world. Visitors are made welcome and given the fullest access to such information as they may require. So is the good name of the College being spread abroad, not merely as a scientific adjunct to local aspects of tropical agriculture, but also as a centre of teaching and research where sincerity of scholarship, integrity of purpose, and a realistic vision for the future, must inevitably play a profoundly important part in aiding humanity in a great practical need—to cultivate its tropical garden.

THE FOUNDATIONS OF EMPIRICAL KNOWLEDGE

By Prof. Herbert Dingle,
Imperial College of Science and Technology

For more reasons than one it is important that those who are engaged in acquiring empirical knowledge should sometimes ask what it is precisely that they are doing, and what is the significance of their work. Much depends on the answer to this question, for in the long run it determines the direction which history takes. High explosive and incendiary bombs may destroy the material products of civilization, but if civilization survives it can produce others : a false idea is a bomb of the delayed action type which may destroy civilization itself. For this reason I have on more than one occasion protested against the false notion, coming unfortunately from authoritative sources within the world of science itself, that what we call empirical knowledge can be acquired without recourse to experience; and that future experience must conform to it.

This illusion is spreading, and philosophers are becoming its victims even more seriously than men of science. For whereas the scientific apostates substitute for experience the comparatively respectable goddess of reason, a vigorous and growing body of philosophers look to grammar as the source and essence of knowledge. Thus, R. Carnap, a leader among this group, maintains that what in science is usually called the ascertainment of an empirical fact by which a given hypothesis can be tested, is more properly described as the reduction, by formal conventional rules of syntax, of certain propositions, which constitute the hypothesis, to "observation-" or "protocol-sentences". These "observation-sentences", however, do not express the possible results of observation: the only criterion for determining their truth or falsity is the possibility of including them within the language used. But if the rules of the language make this impossible, we need not reject the hypothesis: "there always exists the possibility", Mr. A. J. Ayer quotes Carnap as saying, "of maintaining the hypothesis and renouncing acknowledgment of the protocol-sentences". Experience is eliminated altogether: knowledge consists of talking, and whatever you say is true if you do not contradict yourself.

In such a situation the appearance of a book on the foundations of empirical knowledge by a philosopher so acute and well informed in certain directions as Mr. Ayer[*], is a matter of more than casual interest. It may be said at once that while Mr. Ayer has many affinities with the language school of philosophers, he does not share their determination to sidetrack observation: he believes that empirical knowledge originates only in experience, and that if you want to know whether the sentence "mercuric oxide is red" is true or not, you must look and see; it will not help you to study the rules of syntax. For this much must be forgiven him, and it may be that the service which he is thereby rendering to his day and generation is greater than he knows. Moreover, within the limits he sets for himself, he thinks with extreme clearness and expresses himself admirably. The book is a real pleasure to read. There is nothing here of the nebulous incomprehensibility which one often finds in philosophical works, and which one can only hope is a sign of profundity of thought. A sentence of Mr. Ayer's means one thing and one thing only, and you know what that thing is. Sentences are not repeated needlessly, and they succeed one another in perfect logical order. Apart from the rather annoying fact that the references in footnotes to other pages are usually wrong, there can be nothing but praise for Mr. Ayer's presentation of his case.

"My main purpose," Mr. Ayer writes, "has been to resolve the philosophical problems which are commonly brought under the heading of 'our knowledge of the external world'." The fundamental question which he considers is this: when (to use ordinary language) I "observe" a material thing, do I actually observe that thing, or something else (a "sense-datum") related thereto? The latter would appear to be what I really observe because when I look at a shilling, for example, from a certain angle and in a certain light, I see a yellow ellipse, while from another angle I see a black line; but the shilling itself is a white circular disk. A generalization of such facts as these leads some philosophers to say that what we observe are always sense-data, although in special cases the description of the sense-data may be identical with that of the material thing. Mr. Ayer, however, maintains that the question is a purely verbal one. I can always say I observe a material thing if I give to the phrase "material thing" the requisite meaning. In my example I can say that I observed the shilling on each occasion and that it was a yellow ellipse at first and changed to a black line later. It would be a curious way of speaking, but it would not lead us into contradiction.

The question "Do I observe material things or sense-data?" therefore cannot be decided by an appeal to experience as could such a question as "Do I see sovereigns or Bank of England notes?" Empirical facts can be described consistently whichever answer we give, and so the answer simply states what language we intend to use. If we appeal to facts, "it can be only to show that one form of expression is more convenient than the other". Mr. Ayer chooses the sense-datum language because, as he says, it is more convenient, and he proceeds to discuss how material objects can be "constructed" out of sense-data. Other questions also are dealt with, but this is the central one. What the thesis amounts to is this: the only condition a language has to satisfy is that its rules are free from self-contradiction, and between any two such languages the only ground for choice is convenience.

The first thought which all this arouses is that if our aim is merely to avoid contradiction, there is an admirable way of achieving it; namely, by saying nothing at all. This is also extremely convenient. We conclude, then, that philosophers should henceforth remain for ever silent. But Mr. Ayer would doubtless object that of course we want to describe something—that something being, as he admits, experience. But if that is so, then surely there is another ground than convenience for choosing a language; we would prefer the one that enables us to say the most about experience. Here we see the grotesque inadequacy of Mr. Ayer's discussion to his professed subject. He has set out to discuss "the foundations of empirical knowledge"—"the philosophical problems which are commonly brought under the heading of 'our knowledge of the external world' "—without reference at all to the facts that during the last three hundred years there has been a philosophical movement (now called science, thus enabling philosophers to ignore it) which has enlarged the scope and deepened the significance of our knowledge of the external world to such an extent that the knowledge thereof obtained otherwise is by comparison negligible; and, second, that the condition which has made this possible is that men of science have progressively changed their language over and over again, invariably in order to be able to say more and more, and almost, if not quite, invariably from a more to a less convenient one. I will take two outstanding examples of this; but first let us see what kind of language science actually does use.

---

[*] The Foundations of Empirical Knowledge. By Alfred J. Ayer. Pp. x+276. (London: Macmillan and Co., Ltd., 1940.) 10*s.* 6*d.* net.

It is not the language of material things or that of sense-data as Mr. Ayer uses the term. It contains such words as "mass", "brightness", "shape", "motion", which represent groups of components of single sense-data. Jupiter is a material thing, but the mass of Jupiter is not a material thing. If Jupiter were to explode, the mass would continue undisturbed in its orbit at the centre of gravity of the fragments, while the material thing would be scattered in a million other places. The brightness of Jupiter is a function of something extending from the sun to the planet and then to the earth. The shape of Jupiter is a function of the number of times a metal bar at Paris would be contained in certain diameters if Jupiter were not moving with respect to it; and so on.

Each of these words can be ultimately expressed in terms of particular components of sense-data of Jupiter, but science is not in the least interested in putting the components together to make a sense-datum or in 'spelling out' Jupiter in terms of them. The mass of Jupiter is associated not with its brightness but with other masses, to give general laws of mechanics; and the brightness is associated not with the motion but with other luminosities, to give general laws of optics; and what science aspires to do ultimately is to subsume all such laws under a general correlation of all experience. The material thing, Jupiter, and the complete sense-datum of Jupiter, are alike without significance in this process, which, I repeat, has given us all but an infinitesimal fraction of our present knowledge of the external world. Yet Mr. Ayer's discussion of the "philosophical problems" relating to such knowledge makes no reference whatever to it, but concentrates on the manner in which material objects can be described in the language of sense-data.

The first example of changes of scientific language which I will take is probably the best known in the whole history of science—the languages used to describe motion. In the Ptolemaic system, motion meant "change of position with respect to the earth". Copernicus changed this to "change of position with respect to the sun". This was a most inconvenient change—so inconvenient that the ordinary man has never made it; he still speaks of sunrise. Even the astronomer makes it very rarely. In the greater part of his work he talks of the celestial sphere, of right ascension and declination, and so on; and the "Nautical Almanac", the indispensable handbook of applied astronomy, speaks practically without interruption in the Ptolemaic language (a fact which, it may be noted, is consistently overlooked by those who hold scientific progress to have been directed by social needs). But the change enabled the astronomer to say more when he wanted to do so. He could, for example, describe the variations of a planet's brightness in terms of the new language but not in terms of the old, and Newton showed him how he could speak of such diverse things as the movements of the moon and the fall of an apple in the same new tongue. Therefore, because of its greater scope, and in spite of its greater inconvenience, that tongue became the official tongue of science.

Time went on, and astronomers wanted to say still more, so Einstein made another change. He recommended that motion should no longer mean change of position with respect to the sun, but the slope of a world-line in a four-dimensional continuum. In that language you can say all that you said before, and more also. You can describe the motions of the planet Mercury, of light passing near the sun, and of the extra-galactic nebulæ. Is it a convenient language? Well, scarcely: it chokes you to speak it, but it allows you to 'say a mouthful'.

My second example shall be the scientific counterpart of one of Mr. Ayer's own—the only one for which I have space. In order to illustrate the equivalence (apart from convenience) of the languages of material things and sense-data, he instances the well-known fact "that a liquid will seem to have a different temperature according as the hand that is feeling it is itself hot or cold". In the language of sense-data, we have here two different sense-data associated with the same material object, and this contains no contradiction. If, however, we suppose that we are directly experiencing the same material thing with both hands, we appear to obtain the contradictory result that the water is both hot and cold. But "to obtain the contradiction it must also be assumed that the temperature of the water with which the vessel is filled is really the same throughout", and this assumption may be supported by the fact that "it is observed to yield a uniform reading on a thermometer". The contradiction may therefore be avoided by asserting that the water was really hot in one part and cold in the other, and hence that thermometer readings, made with the precautions usual in science, give untrustworthy indications of temperature. This would be the account of the matter in the material object language, and, according to Mr. Ayer, it is equivalent to the account in the sense-datum language in everything but convenience.

Again one cannot help asking: What about the scope of the languages? If thermometers cannot be trusted, then the only describable thermal phenomena are our direct sensations of heat and cold. Here is a pretty science of heat! Presumably the fact that the thermometer reads higher in boiling salt solution than in boiling water is "knowledge of the external world", but since our bodies would detect no difference we cannot connect this fact with the difference that we feel between a winter's and a summer's day. The latter is a difference of temperature, but we must invent a new and independent language to express differences of thermometer readings.

What has science done with phenomena of this kind? It has begun by defining the temperature of a body as the equilibrium reading of a thermometer—a mercury thermometer, say—immersed in the body. The difference in the sensations felt by the two hands must then be explained by supposing that they had different temperatures when immersed, and this is consistent with all other relevant facts available. The definition is not so convenient as that of direct feeling, but it enables us to connect together—to "speak about" —a wider range of phenomena. But the range is still unduly limited for the physicist. He cannot measure the temperature of a bunsen flame or liquid air with a mercury thermometer, so he changes his language to one in which temperature means the reading of a 'perfect gas' thermometer. A perfect gas never changes its state, however hot or cold it gets, so that in the new language we can talk about the temperature of anything which the universe may contain. As for convenience, there is, it is true, a slight disadvantage in the fact that neither a perfect gas nor the only equivalent substitute—a reversible heat engine—can possibly exist, and we have to do the best we can with a real gas and make fairly elaborate corrections for its 'reality'. However, the physicist puts up with this, for he has only a pallid interest in convenience: it is the scope of his language that stirs his blood.

One would think that he had now gone far enough. But no; he soon becomes dissatisfied with the perfect gas thermometer and gives the word "temperature" a new meaning: it next stands for "the average kinetic energy of the molecules of a body". This is quite a new departure. In terms of this language he says that the temperature of interstellar matter is something greater than 1000° C., whereas he is quite confident that if a gas thermometer were placed in the matter it would read something near the absolute zero. Again the change is not made for convenience. If anyone thinks so, a page of Willard Gibbs will provide an infallible, though not a painless, corrective. The change is made solely because it enables us to speak of thermal and mechanical phenomena in the same language, and so enlarges our scope of expression.

So when Mr. Ayer tells us that a language which makes a thermometer reading an untrustworthy indication of temperature is equivalent in all but convenience to one in which a thermometer reading is trustworthy, the scientist must beg permission to dissent. It is true that, according to the latest definition, a thermometer no longer indicates temperature, but it is not untrustworthy, for we know why, and can predict when, it will fail. In interstellar space the matter is so rarefied that the thermometer receives impacts from the molecules very infrequently, and radiates away each increment of the acquired energy before the next arrives. To know this is to increase our knowledge, while to reject the thermometer in favour of direct bodily sensations is drastically to restrict it.

The immense and awe-inspiring knowledge of the external world which we now possess, and which continues to grow at an almost incredible rate, is indeed a matter of the deepest concern. What does it all mean? Is it a discovery of unalterable fact, or a creation which our reason can transform as experience grows? How comes it that by taking thought in a particular way, unknown to the ancients, we can add unlimited cubits to our stature and determine the course of the world's history? What exactly are we doing, and what are the potentialities of the ideas to which we are led, when we set reason to operate on experience in the manner which has yielded the bulk of the empirical knowledge which is ours to-day? The man of science, immersed in the process itself, rarely has the time or the aptitude to ponder these questions. He may realize their importance, but it is his chief function to produce the knowledge, not to assess it or discover its nature. For that we must look to the philosopher —to the man trained in the processes of accurate logic and versed in the history of human thought. On the philosopher, in the modern sense of the word, rests a great responsibility, perhaps the most urgent responsibility in the world to-day—that of laying bare the foundations of empirical knowledge so that we may use it with foresight instead of a blind understanding. And when we turn to what one of the most able and promising of the younger philosophers has to tell us on this all-important question, we find that it is mainly a set of speculations on how to translate from one ineffective language into another. If Mr. Ayer were a less significant figure we might in silence leave his book to psychologists, for whom the question it discusses, and perhaps the discussion itself, has some academic interest. It is because of the possibility that he might yet bring his great talents to bear on the problem which he thinks he has already considered that his book deserves serious attention.

OBITUARIES

Prof. H. S. Hele-Shaw, F.R.S.

Henry Selby Hele-Shaw, who died on January 30 at the age of eighty-six, combined in an unusual degree the academic and the inventive mind. Educated privately, he served an apprenticeship for four years as a mechanical engineer, after which he won a Senior Whitworth Scholarship and with it proceeded to University College, Bristol. On completing the course, he was appointed lecturer in mathematics and engineering at Bristol, and a few years after, in 1881, was made professor of engineering. Four years later he was appointed the first professor of engineering at University College, Liverpool. He held this post until his resignation in 1904, when he was appointed first professor of engineering in the Transvaal Technical Institute; after a year he was made principal of the Institute. Soon afterwards the Secretary of State for the Colonies appointed him organizer of technical education in the Transvaal.

On returning from South Africa in 1906, Hele-Shaw set up a consulting practice in Westminster and carried this on with great success until his death. He was president of the Institution of Mechanical Engineers in 1922, and president in 1915 of Section G (Engineering) of the British Association. He delivered the James Watt Anniversary Lecture in 1902, the subject being "James Watt, Inventor". He was an LL.D. of St. Andrews, a D.Sc. of Bristol, and a D.Eng. of Liverpool.

While at Liverpool Hele-Shaw was largely responsible for collecting funds for the endowment of the chair of engineering and for the building of the Walker Engineering Laboratories. It was here, too, that he carried out his experimental work on stream-line flow which established his reputation as a scientific investigator, and for which he was elected a fellow of the Royal Society in 1899.

It was during his early days at Liverpool that Hele-Shaw's inventive ability began to develop. He was much interested in the subject of friction and delivered four Cantor Lectures on the subject in 1886. It was about this time that he invented his well-known multiple-disk clutch. He also became very interested in road transport, and in 1897 organized the Liverpool trials of commercial vehicles for the Liverpool Automobile Club and Self-Propelled Traffic Association. He became president of the Institution of Automobile Engineers in 1909.

After taking up consulting practice, Hele-Shaw developed several important inventions, among which his hydraulic variable-speed gear, the stream-line filter, and the Victaulic pipe joint are especially worthy of mention. His most recent important work was on variable-pitch airscrews.

As an organizer of technical education Hele-Shaw did valuable work, especially in more recent years in connexion with the introduction of National Certificates. In 1920, when the Board of Education approached the Institution of Mechanical Engineers with a view to collaboration in a certificate scheme to take the place of the old Science and Art Certificates, Hele-Shaw was chairman of the Education Committee of the Council, and it was largely due to him that the scheme was adopted. He was the first chairman of the Joint Committee and held this post until 1937.

Until the end he was a remarkably vital character. As a lecturer he was breezy, humorous, and unconventional, and as such will be happily remembered by more than one generation of students.

A. H. Gibson.

Sir Pendrill Varrier-Jones

By the tragically sudden death on January 30 of Sir Pendrill Varrier-Jones in his fifty-eighth year the medical profession has lost a pioneer in the full tide of his activities. The only son of Dr. C. Morgan Jones of Glamorgan, he was educated at Epsom College and St. John's College, Cambridge, where he was a foundation scholar and prizeman, graduating in the first class of the Natural Sciences Tripos, Part 1. Proceeding to St. Bartholomew's Hospital he qualified there and became house physician. On the completion of his term of office he returned to Cambridge for pathological research under Sir German Sims Woodhead. At the outbreak of the War of 1914-18 the Cambridgeshire tuberculosis officer joined the R.A.M.C., and Varrier-Jones, who was graded as unfit for military service, was asked to undertake his work temporarily. He accepted with some reluctance, for hitherto his interests had been directed purely to laboratory research.

It is difficult to realize to-day the total inadequacy of the treatment of pulmonary tuberculosis fifty years ago. Too often the out-patient at hospitals merely received some cod liver oil and cough mixture, after waiting for some hours at the risk of infecting other patients. Open-air sanatoria, both in Norfolk, were started in the middle 'nineties by Dr. Jane Walker and by Dr. Burton-Fanning. Then King Edward VII by his question "If preventible why not prevented ?" galvanized the authorities into some sort of activity, resulting in the establishment of the sanatorium at Midhurst. Though interest in the subject had now been aroused, no large-scale plans were made until the National Health Insurance Act, with the consequent provision of hospital and dispensary facilities.

The point on which Varrier-Jones seized was the great liability of the patient to relapse on his return to the environment in which he had contracted the disease, thus nullifying the efforts that had been made. Engaging the support of Clifford Allbutt, Sims Woodhead and Humphry Rolleston, he started a village settlement at Bourn in Cambridgeshire in 1915 with only one patient in a shelter, but filled with a vision of the future. That vision was for the patient to pass through all the stages of hospital and sanatorium treatment, and to be provided with occupation suited to his state of health. When afebrile he was to work at a trade for the trades union rate of wages. He would reside in a hostel, or if married, in the village settlement with his wife and family. If at any time his health relapsed he would be sure of prompt and expert treatment in the institution. And Varrier-Jones lived to see that audacious vision realized. In 1918 much more extensive premises were obtained at Papworth Hall, and gradually the institution expanded over five hundred acres of land, complete with administrative blocks, hospital wards, a large sanatorium, laboratories and a research institute, a village settlement of more than a hundred cottages, hostels for men and women, and factories with annual sales which together with those of Enham, have now reached nearly half a million pounds annually. This might have been considered sufficient for the activities of any man, but they were not enough for Varrier-Jones. He was honorary medical director of the Enham Village Centre for ex-Service men, replanned the Preston Hall Village Settlement at the request of the British Legion, and advised on the establishment of a village settlement near Dublin. His latest ambition was to add a teaching department to Papworth, and he was writing enthusiastically to some medical supporters about this only an hour before his death.

Enthusiasm was indeed the keynote of his character, reinforced by tenacity and tireless energy. He has been well described as a Celt with all the Celt's fire and imagination and with the long black hair and gestures of an impresario. In early life he was nicknamed the Pendragon, and he adopted this as the trade-mark of the Papworth goods. Sir Clifford Allbutt said of him that he restored hope to those who had lost it, and there is no doubt that his great success was due to the force of his personality. So individual were his gifts that it is difficult to see who can succeed him, for clinical insight and great business capacity are seldom united. Yet there can be no doubt that his plan is capable of wide extension and would greatly help to solve the problem of pulmonary tuberculosis, converting damaged lives from a liability to an asset for the community. He was strongly of opinion that the community by insisting on the notification of tuberculosis thereby accepted responsibility for those on whom it had imposed this handicap. It was his proud boast that no child born in the settlement of a tuberculous parent had ever developed tuberculosis.

The value of his work was publicly recognized by a knighthood in 1931, the fellowship of the Royal College of Physicians in 1934, and the Weber-Parkes Prize in 1939. W. LANGDON-BROWN.

Prof. V. Putti

PROF. VITTORIO PUTTI, the eminent orthopædic surgeon, who died recently, was born on March 1, 1880, at Bologna, where he received his medical education and qualified in 1903. For eleven years he was assistant to Alessandro Codivilla at the Rissoli Institute at Bologna, of which he became director in 1914. In 1909 he was appointed lecturer in orthopædics and in 1914 professor in this subject at his Alma Mater. In 1917 he founded the journal *Chirurgia degli Organi di Movimento*, to which *Bibliografia Ortopedica*, founded by him three years later, containing summaries of current orthopædic literature, formed a useful supplement. Putti introduced many new orthopædic operations and made numerous valuable contributions to the literature of his speciality, particularly on congenital dislocation of the hip, osteoarticular tuberculosis, for the electrotherapeutic treatment of which he founded the Codivilla Institute at Cortone d'Ampesso as a branch of the Rizzoli Institute, diseases of the vertebral column, transplantation of muscles and Madelung's deformity. Enjoying an international reputation, he received invitations to lecture in several foreign countries including Great Britain, where he had many friends. J. D. ROLLESTON.

WE regret to announce the following deaths :

Dr. Rendel Harris, F.B.A., the well-known biblical scholar, archæologist and Orientalist, on March 1, aged eighty-eight.

Prof. C. R. Lanman, professor of Sanskrit at Harvard University during 1880–1937, and a corresponding member of the British Academy, who was a distinguished Orientalist and authority on ancient Indian languages and literature, aged ninety.

Mr. C. A. Ludwig, associate plant physiologist in the Division of Soil Microbiology of the Bureau of Plant Industry, U.S. Department of Agriculture, on January 7, aged fifty-four.

Dr. Adolpho Lutz, for many years chief of the department of medical zoology at the Institute Oswaldo Cruz, Rio de Janeiro, aged eighty-four.

Dr. C. B. Ticehurst, the distinguished ornithologist and editor of *Ibis*, on February 17, aged sixty.

NEWS AND VIEWS

Mineral Nutrition of Plants

THE 1,000 dollar prize of the American Association for the Advancement of Science has been awarded to Dr. D. I. Arnon of the University of California for a paper read at the Philadelphia meeting of the Association on behalf of a seven-man laboratory team under the guidance of Prof. D. R. Hoagland. Since Prof. Hoagland's first experiments upon the mineral economy of Nitella—where it was shown that the growing cell swept most of the ions out of the surrounding medium, piling them up within its own sap, although thus doing work in accumulating them against the concentration gradient, whilst the mature or senescent cell indicates its advancing age by an inability even to retain or maintain this internal solute concentration—the workers in Prof. Hoagland's laboratory have rapidly established quite a new conception of the mineral nutrition of the higher plant. This has thrown a new light upon the high concentration of mineral ash in growing tissues and has thus made clear to agriculturist, and still more to horticultural and forest botanist, what large reserves of minerals may be available in adult regions of the plant, to be utilized over again after release and transfer from adult to growing regions.

Prominent in this work has been Dr. F. C. Steward, working first at the University of Leeds and later at Birkbeck College, London. In some of this work a technique has been employed with great success of introducing a new ion, bromine, and following the conditions governing its absorption and distribution. Dr. Steward has also shown, by his studies at the Tortugas, that the students of the salt accumulation of the large cells of Valonia cannot afford to neglect consideration of its growth phases or of the conditions under which it is maintained during the period of the experiment. He has also advanced our general knowledge of salt accumulation by his utilization of spectrometer methods which permit a rapid quantitative control of the rates of ionic interchange. Dr. Arnon himself has contributed particularly to our knowledge of the conditions governing the relative utilization of ammonium and nitrate sources of nitrogen; he has also been associated with a series of investigations upon the significance of relatively rare elements in plant nutrition, such as copper, zinc, manganese and molybdenum. Altogether, the work recognized by the American Association in this award represents a contribution which stands very high in the esteem of plant physiologists and in which the English contribution, associated with Dr. Steward and his collaborators, reaches the same high standard, both of experimental technique and critical interpretation.

Abyssinian Ornithology

THE invasion of Abyssinia and Somaliland has given members of the British army who are ornithologically minded a unique opportunity for observation in an area little explored by naturalists, and the outcome may prove as useful as the information noted by ornithologists stationed in Egypt in the War of 1914–18. Cheesman (*Ibis*, 1935) made a detailed survey of bird life in north-west Abyssinia, where he collected for the British Museum when H.M. Consul. The Abyssinian flappet lark, producing a rattle-like wing-sound when rising in song, is resident on the high plateau, the white-collared pugin, the great hammerkop and the African barn-owl nested at the British Legation at Addis Ababa. At Lake Tana there are black crakes, paaw bustards, egrets, buff-backed herons, a colony of white-bellied storks, spur winged geese, tufted duck, pochard, white-eyed duck, sea eagles, ospreys, marsh-harriers and lesser black-backed gulls. Wheatears are frequent passage migrants on the big grass plains, and these include the eastern black-eared wheatear.

The avifauna of the region includes many of its own forms as well as European birds on migration and rarer British species like the wood sandpiper and gull-billed tern, but there remains an enormous scope for field studies of bird habits in addition to compiling lists and skins. Cheesman obtained a new race of Cisticola or striped grass warblers at Wanbera, not previously visited by ornithologists, comprising a dozen species. Bird life is probably richest near the waters, like the Blue Nile and Lake Tana, with a wealth of waders, duck and fishing birds, but the colony of red-legged choughs at Simen is of considerable scientific interest, for the nearest colony to this is apparently at Cyprus. The Ethiopeans have never been greatly interested in their fauna, and although the chief dangers to bird life are the big fires, the protection of the larger insectivorous birds would no doubt help their agriculture against the locust and other pests.

Earthquake in Greece

ABOUT 5.55 a.m. local time on March 1, a severe earthquake shook many towns and villages in northern Greece. At Larissa, in Thessaly province, houses were destroyed, telephone and telegraph and other buildings damaged and some streets blocked by debris. Many people were frightened and left their houses. One person has been reported killed and five injured. Extensive damage was caused at Elassona, and the epicentre may have been near this place. The shock was also felt at Volo and Lamia, Kanditsa and Trikkala. In the whole district there may be as many as 15,000 people homeless as a result of the earthquake, although complete details are not available at the time of writing. Rescue work is being undertaken by the local authorities and by British soldiers and airmen.

The earthquake follows fairly recent earthquakes in Rumania and Cyprus. The epicentres of Greek earthquakes appear to bear some relation to the great lines of fracture to which the country owes its outline. Earthquakes are particularly frequent around the narrow gulf which separates the Peloponnesus from the mainland, and in the peninsula of Messene in south-western Greece, but in the past they seem to have been less frequent in the area now affected. It will be remembered that severe earthquakes took place in Greece on July 21, 1938, near Oropos, when about seventeen people were killed and eighty injured, and on April 17, 1940, near Patras, and Missolonghi, though on this latter occasion no casualties were reported.

Leadership

The Lees Knowles Lectures on "Generals and Generalship" delivered at Trinity College, Cambridge, in 1939, by General Sir Archibald Wavell and recently published in *The Times*, have now been reprinted and published as a pamphlet, with a foreword by General Sir John Dill (Times Publishing Co., Ltd., Printing House Square, London, E.C.4. *6d.*). Dealing essentially with the principles of leadership and the relations of man to man, they have an interest that extends far beyond military circles. Sir Archibald Wavell takes a quotation from Socrates as giving the best definition of the essential qualities of a commander, and agrees with him in placing administration first, while tactics or the handling of troops in battle comes last. Character, or knowing what he wants, with the courage and determination to get it, and a genuine interest in, and knowledge of, humanity come first in the moral qualities of a leader, while in the mental qualities, commonsense, or the knowledge of what is and what is not possible is the most important. The bearing of this analysis on problems of technical administration generally will be readily perceived, and Sir Archibald's remarks on the commander and his troops are equally suggestive and stimulating. There are many in industry who might well apply Sir Archibald's simple rules that a general should never try to do his own staff work, and that he should never let his staff get between him and his troops. Tradition and discipline, he holds, are the root of the matter in relations between the general and his men.

The third lecture, in which General Wavell deals with the relations of higher commanders with the statesmen who direct them, is in some ways the most significant in its suggestions for removing the friction between civil and military which tends to be a feature of democracy in war. Making the point that knowledge of the mechanics of war, not of the principles of strategy, distinguishes a good leader from a bad, and that both war and politics have been too highly specialized to be interchangeable professionally, Sir Archibald urges that a better understanding between the commander and the politician is essential for the conduct of modern war. The qualities which lead to excellence in generalship or in statesmanship have indeed much in common and should promote the thoughtful study of the past, the receptive mind and the patient understanding of each other's difficulties which are the key to mutual knowledge and understanding. General Wavell's lectures, which show all the lucidity of exposition and thought already apparent in his life of Lord Allenby, should do much to promote such understanding in all classes of our society, and enhance the confidence which we place in our present-day commanders.

Function of Treaties

Mr. A. D. McNair's admirable pamphlet "War and Treaties" (Oxford Pamphlets on World Affairs, No. 32. Oxford: Clarendon Press. *3d.* net) makes a most pertinent contribution to discussions on the new world order to be established after the War. In the poverty of international legal institutions, a treaty has to serve too many purposes, and this has largely contributed to the recent shocks to the sanctity of treaties and the shattering blows to the mutual good faith which lies at the very basis of our society. No principle of law has received such universal homage and is so widely spread as the rule *pacta sunt servanda*—agreements must be kept. Moreover, while a treaty can be violated not only by a clear breach or an unjustified denunciation but also by the much subtler means of a claim by a party to a treaty to be entitled to give it his own interpretation, once Governments have been led to refer a dispute concerning interpretation to an international tribunal, it is most rare for them not to carry out the decision. While the sanctity of treaties is a fundamental principle of international relations if force is to be excluded, treaties must contain within themselves the machinery for the revision of their provisions, or such machinery must be created outside them and be applicable to them. The problem of reconciling stability with means of peaceful change, of finding a mean between rigidity and flexibility, has, however, so far baffled international society and has been responsible for one crisis after another.

It is futile, Mr. McNair urges, to attempt to superannuate war unless we can substitute some peaceful machinery for achieving one of the common objects of war—changes in the *status quo ante*. That peaceful machinery, if it is to amount to more than revision by consent, must involve a willingness to accept the judgment of some kind of international tribunal or authority upon the equity of a claim, instead of insisting on being judge in one's own cause. Moreover, before the 'Family of Nations' can become a true society, some control must be placed upon the present licence in treaty-making. In view of the far-reaching danger to society which is implicit in a bad treaty, society must sooner or later acquire some kind of initial control upon treaty-making. Many treaties are more than the concern only of the contracting parties. The lack of any machinery for the supervision of treaty-making, and the paucity of rules upon the legality of treaties, are a serious defect in our present system. Commenting on the progress of the International Labour Organisation, Dr. McNair suggests that introduction of its practice of using non-governmental delegates, with the resultant encouragement of a more co-operative atmosphere, into a wide field of international affairs should make an important contribution to the development of a real international society by assisting the removal from international law of some of these imperfections and immaturities in regard to treaties.

Further Amendments to the Pharmacopœia

FURTHER amendments, due to conditions arising out of the prosecution of the War, have been made to the "British Pharmacopœia". They have been made effective by notices in the *Gazettes*. Owing to the closing of the principal source of supply of squill, namely Sicily, sanction is now given for the use of Indian squill (*Urcinea indica*) in place of *Urcinea scilla* in the preparation of oxymel, vinegar and tincture of squill. In the case of valerian, which was formerly obtained chiefly from Belgium, Holland and Germany, the use is now permitted of Indian valerian (*Valeriana wallichii*) in place of *Valeriana officinalis* whenever valerian is prescribed or demanded. Another amendment sanctions the use of sodium lactate instead of glycerin in the preparation of poultice of kaolin, the object being to assist in the conservation of supplies of glycerin. Facilities have been given by the appropriate Government departments for the importation of Indian squill and Indian valerian.

Institute of Chemistry

AT the annual general meeting of the Institute of Chemistry held on March 3, the president, Dr. J. J. Fox, C.B., the Government Chemist, presented the report of the Council, in the course of which he stated that the professional examinations of the Institute had continued, and the membership had increased by more than 220 during the year. The increase in the numerical strength of the Institute since 1914, he said, has been remarkable ; it has been multiplied more than five times, namely, from 1,454 to 7,775. In the meantime, unemployment among the members has never exceeded 3 per cent and at the present time is less than 1 per cent. Industry was far more fully staffed with chemists in September 1939 than in July 1914, but the Institute had been of much assistance to the Government in supplying chemical personnel during the War. Dr. J. J. Fox was re-elected president ; and the Meldola Medal for 1940 was awarded to Dr. E. R. H. Jones, assistant lecturer in organic chemistry in the Imperial College of Science and Technology.

Food in War-time

An important article, "Food in War Time", by Lord Horder in the *Quarterly Review* of January emphasizes the way in which food policy in war could be utilized to make a permanent contribution to national fitness, and the part which science has to play in pursuing this objective. Science, Lord Horder points out, supports a return to the diet that kept our fathers and forefathers fit, and assures us that in doing so we are on sound and rational lines. The memorial sent to the Prime Minister last May, of which Lord Horder was a signatory, urged that milk, potatoes, fresh vegetables, cereals, fats and sugar, should be kept constantly in mind as the basis of fitness. The whole consumption of the first three could be grown at home, and better use of our home-grown fruit would enable us to reduce considerably our imports of fruit. We could grow all the oats we need and much more of the wheat and barley.

A comprehensive food policy connotes close and constant co-operation between the Ministries of Food, Agriculture and Transport ; intelligent co-operation on the part of the consumer is essential to success in a campaign for feeding the people properly in war-time, and Lord Horder pleads for greater use of the educational opportunities given by war-time conditions. By planning wisely we could rapidly enable the town worker to retrace his steps in the matter of diet, making more accessible the wholesome foods which his ancestors ate and which he discarded when he became urbanized, and at the same time making less available the more unsuitable foods which have taken their place for the last two generations. In such planning the Minister of Food has the guidance and backing of science and medicine, and this contribution to building a better social and economic system could start now.

Merseyside Naturalists' Association

AT the third annual meeting of the Merseyside Naturalists' Association, held at the Liverpool Museum on February 23, Mr. R. K. Perry, keeper of vertebrates at the Museum, was elected president, Dr. J. C. P. Miller of the University of Liverpool, chairman, and Mr. Eric Hardy, honorary secretary. Since 1939 membership and funds have doubled, activities have been continued in full, with a well-attended programme of meetings ; additions to the local flora have been made to the national herbaria at Kew and the British Museum. The president exhibited a collection of skins of rare British mammals, detailed reports were presented of bird surveys at Leigh Flashes, Rufford, Puffin Island, the Great Orme's Head, Corwen, etc., and the MS. of the Association's proposed handbook on the birds of the area. As this is by far the largest natural history society in the area it was agreed to continue activities so far as the War permitted.

American Geographical Society: Medal Awards

Two medals have recently been awarded by the American Geographical Society. Dr. R. C. Murphy, of the American Museum of Natural History, receives the Cullum Geographical Medal for distinguished work on the migration and habits of oceanic birds, which are his speciality. He is the first ornithologist to receive this medal, which has previously been awarded thirty-five times. Earlier recipients have included Admiral Robert E. Peary, Sir John Murray and Prince Albert of Monaco. Prof. C. O. Sauer, of the University of California, receives the Charles P. Daly Medal, in recognition of his outstanding contributions to geography, especially in the fields of land classification and land utilization. Among the twenty-nine recipients of the Daly Medal have been Vilhjalmur Stefansson, Capt. Robert A. Bartlett and Dr. Roy Chapman Andrews.

Institution of Mechanical Engineers: Awards

The following awards have recently been made by the Institution of Mechanical Engineers: *Thomas Hawksley Gold Medal* to Dr. F. D. Smith and bronze replicas of the Medal to his co-authors, E. H. Lakey, H. Morgan, and C. A. Luxford, for the following papers which were presented as a group: "The Admiralty Cathode Ray Oscillograph Engine Indicator" by F. D. Smith, E. H. Lakey and H. Morgan; "Basic Principles in the Design of Cathode Ray Oscillograph Engine Indicators" by F. D. Smith; "Stress Measurement by Magnetostriction" by F. D. Smith and C. A. Luxford. *George Stephenson Prize* to Dr. R. C. Plumb and Prof. A. C. G. Egerton, for their paper on "A Criterion for Knock in Petrol Engines". *Dugald Clerk Prize* to G. W. A. Green for his paper on "Fuel Injection in Oil Engines in Relation to Combustion". *Water Arbitration Prize* to Dr. E. G. Holley for his paper on "The Static and Fatigue Torsion Strengths of Various Steels with Circular, Square, and Rectangular Sections". *Starley Premium* to Prof. W. T. David and Dr. A. S. Leah for their paper on "Fuel Economy in Petrol Engines". *Herbert Akroyd Stuart Prize* to Dr. G. F. Mucklow for his paper on "Exhaust-Pipe Effects in a Single-Cylinder Four-Stroke Engine", and R. W. Zdanowich and T. S. Wilson for their paper on "The Elements of Pendulum Dampers". *Thomas Lowe Gray Prize* to Prof. W. Kerr, Dr. J. F. Shannon and Dr. R. N. Arnold for their paper on "The Problems of the Singing Propeller". *T. Bernard Hall Prize* to F. Dollin for his paper on "Investigation of Steam Turbine Nozzle and Blading Efficiency".

An Active Sunspot

After several weeks of generally diminished sunspot activity, a large sunspot developed rapidly on the sun's disk between February 26 and 28. The spot was apparently associated with marked chromospheric activity on the latter date. The time of central meridian passage of the disturbed area was February 27·3.

Royal Society of Edinburgh: New Fellows

The following have been elected ordinary fellows of the Royal Society of Edinburgh: Dr. H. A. Cookson, Sunderland Royal Infirmary; Dr. C. A. Coulson, Mathematics Department, University College, Dundee; Mr. Atulananda Das, Imperial Forest Service, Shillong, Assam; Dr. J. N. Davidson, Biochemistry Department, University of Aberdeen; Prof. E. C. Dodds, Courtauld Institute of Biochemistry, Middlesex Hospital, London; Dr. E. Finlay-Freundlich, Department of Astronomy, University of St. Andrews; Mr. A. G. L. Gerard, assistant superintendent, Tongland Power Station, Kirkcudbright; Mr. J. C. Gibson, assistant secretary, Air Ministry, London; Mr. James Gray, 7 Spence Street, Edinburgh; Mr. R. L. Gwilt, secretary, Scottish Widows' Fund, Edinburgh; Mr. James Jamieson, engineer and manager, Edinburgh Corporation Gas Department; Prof. Mangalore Kini, Medical College, Andhra University, Vizagapatam; Mr. A. C. Marshall, director of education, County of Clackmannan, Alloa; Dr. A. G. Mearns, Department of Hygiene, University of Glasgow; The Hon Lord Moncrieff, senator of the College of Justice in Scotland, Edinburgh; The Hon. Lord Murray, chairman of the Scottish Land Court, Edinburgh; Dr. Ivan Parnell, Institute of Helminthology, Macdonald College, Quebec; Dr. E. G. V. Percival, Department of Chemistry, University of Edinburgh; Dr. F. E. Reynolds, pathologist to the Municipal Hospital, Glasgow; Mr. J. J. Robertson, rector, Royal High School, Edinburgh; Dr. A. D. Ross, Department of Civil and Mechanical Engineering, University of London; Dr. H. Scarborough, Department of Therapeutics, University of Edinburgh; Mr. A. Steuart, lately president, Royal Scottish Society of Arts, Edinburgh; Dr. R. L. Sutton, assistant professor of dermatology, Kansas Medical School, Kansas City, Missouri, U.S.A.; Dr. George Trapp, biology master, George Watson's Boys' College, Edinburgh; Dr. D. A. Walker, teacher of science, Daniel Stewart's College, Edinburgh; Mr. J. E. Wilson, senior research officer, Ministry of Agriculture and Fisheries, Edinburgh.

Announcements

Prof. James B. Conant, the distinguished organic chemist and president of Harvard University, who is a member of the U.S. National Defense Research Committee, is visiting Great Britain to confer upon collaboration in the scientific field.

Dr. L. J. Spencer, formerly keeper of minerals in the British Museum (Natural History) has been awarded the Roebling Medal of the Mineralogical Society of America.

The Swammerdam Medal for 1940 has been awarded to Prof. G. W. Grijne of Amsterdam, the Nestor of Dutch physiologists. The six previous recipients have been K. T. E. von Siebold (1880), Ernst Haeckel (1890), K. Gegenbaur and Hugo de Vries (1910), Max Weber (1920) and H. Spemann (1930).

According to a wireless dispatch to the *New York Times*, Prof. Paul Langevin, formerly professor of experimental physics in the Collège de France, who had been detained in prison in Paris, has been released on parole for reasons of health. Prof. Langevin was deprived of his professorship because of his political activities.

The Ministry of Agriculture is anxious to give every possible help to gardeners and allotment holders in the "Dig for Victory" campaign. The season for planting is just beginning, and it is of the first importance that the right crops be grown so as to avoid the production of surplus perishable summer vegetables. Plans made now mean plans for next winter, and adequate space must be allocated to the growing of the valuable potato, onion, carrot, beetroot and other crops that can be stored, and used as substitutes for foodstuffs that are normally imported. A suitable lay-out and cropping plan is given in Growmore Leaflet No. 1, which can be obtained free from most local authorities, while for more specialized information attention may be directed to Leaflets No. 32 on seed potatoes and No. 57 entitled "Tomato Growing is not Difficult".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Linkage between the Repeating Units in the Starch Molecule

IN an earlier paper[1] we presented evidence which indicated that the starch molecule is made up of a large number of repeating units (each consisting of an unbranched chain of some thirty glucose units) combined together in such a way that the free reducing group of one unit is linked glucosidically with a hydroxyl group of the adjacent unit. It is now apparent that in the derivatives of starch we have examined, the hydroxyl group concerned in the glucosidic union of the repeating units, is a primary alcoholic group situated at C_6 of one of the glucose residues. The occurrence of this mode of linkage was indicated previously[2] and was suggested simultaneously by Freudenberg and Boppel[3]. In this connexion it may be mentioned that we have never advocated the views on the structure of starch recently attributed to us by Kurt Meyer[4], and that, on the other hand, if each of the units represented in the formula suggested by Meyer is considered to contain some thirty glucose residues, his formula becomes identical in type with the structure we have advocated[1].

The new results are derived from the following experiments. Methylated rice starch was disaggregated[1], giving material of low molecular weight, specially suitable for experiments on the mode of linkage in that it readily undergoes complete methylation. On hydrolysis, the fully methylated derivative gives rise to 2 : 3 : 6-trimethyl glucose, 2 : 3 : 4 : 6-tetramethyl glucose (end-group) and dimethyl glucose. It is evident that one of the two free hydroxyl groups of the dimethyl glucose represents the point of junction of the repeating units. Examination of the dimethyl sugar has revealed that it consists almost entirely of 2 : 3-dimethyl glucose, from which it follows (since C_4 is involved in the linkages of the glucose residues within the unit) that the repeating units are connected through C_6 of one of the glucose residues. The yield of dimethyl glucose (3 per cent) is consistent with the view that one such linkage exists per repeating unit. The exact position of the particular glucose residue in the chain of the repeating unit is not yet known and the problem of its determination is of special importance in connexion with enzymic degradation of starch[5]. It is to be observed also that the present evidence concerns the linkages in the disaggregated derivative, and the further question, whether all the linkages connecting repeating units in the original starch are of similar type, must await further investigation.

The following evidence served to identify the 2 : 3-dimethyl glucose. (*a*) It forms both furanose and pyranose methyl glycosides, since in cold methyl alcoholic hydrogen chloride the rotation drops from $[\alpha]_D + 59°$ to $-30°$, and in boiling methyl alcoholic hydrogen chloride it rises to $+75°$. (*b*) The amide of the corresponding dimethyl gluconic acid gives a negative Weerman reaction with sodium hypochlorite. The hydroxyl at C_2 is therefore methylated. (*c*) The *p*-toluene sulphonyl derivative of the dimethyl methyl glucoside, when heated with sodium iodide in acetone at 100°, gave sodium *p*-toluene sulphonate (yield 87 per cent of the theoretical), and this was corroborated by an estimation of the iodine content of the syrup isolated after removal of the sodium *p*-toluene sulphonate. C_6 therefore carries a free hydroxyl group[6] and this, in conjunction with the other evidence, fixes the constitution as 2 : 3-dimethyl glucose.

The quantitative aspect of these results shows that other dimethyl glucoses cannot have been present in more than minute amounts, insufficient to affect the conclusions outlined above.

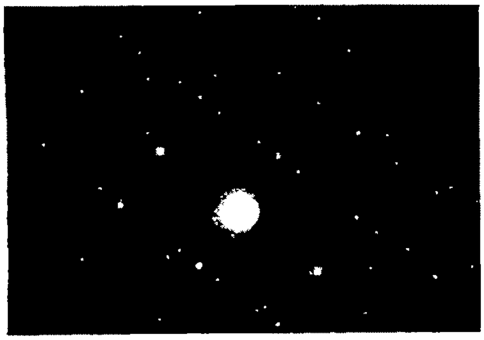
A New Method of obtaining the *N* Pattern of Electron Diffraction

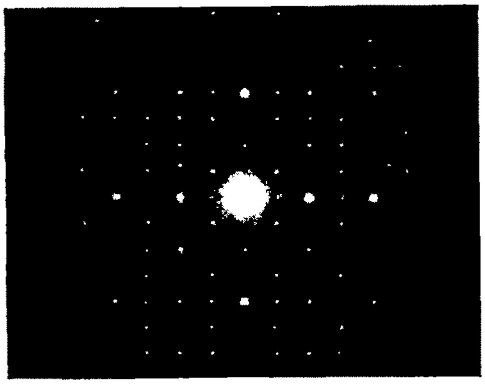
THE *N* pattern of electron diffraction was first obtained from a thin piece of mica. It has not been obtained for many substances because of the technical difficulty of preparing single crystal films of suitable thickness for electron penetration.

I have discovered a method of preparing two-dimensional films of various substances, and a big field of investigation by electron diffraction is now opened.

The *N* patterns shown in the accompanying photographs were obtained by the new method of preparation; the films, which may properly be called synthetic, are laboratory products and are made by allowing chemical reactions to take place under physical control.

Thin films of water or hydrochloric acid were first prepared by immersing a platinum wire gauze in water or in the acid (12 *N*) and then withdrawing it. Upon bringing such films into contact with a clean piece of potassium or calcium, chemical reaction immediately takes place, giving films of the reaction products adhering to the gauze and highly suitable for transmission electron diffraction experiments. The upper pattern is from a potassium bicarbonate ($KHCO_3$) single crystal produced by the method





described, the reaction being allowed to take place between potassium and water in the presence of air; the lower pattern is from a calcium chloride ($CaCl_2{\cdot}2H_2O$) single crystal similarly obtained but utilizing the reaction between calcium and 12 *N* hydrochloric acid.

The potassium bicarbonate crystal has already been studied by X-rays and the data serve well for comparison here. The dimensions of the reciprocal lattice determined by the *N* pattern here obtained are: $a^* = 15\cdot4$ A. and $b^* = 5\cdot72$ A.; X-ray work gives $a = 15\cdot01$ A., $b = 5\cdot69$ A., and $\beta = 104^\circ 30'$ (monoclinic structure). The new method of preparing films thus gives results in good agreement with X-ray findings.

As is well known, structure determination from the *N* pattern is more definite than that by X-rays, hence the present work is in this respect also of significance. Due to the highly hygroscopic nature of $CaCl_2{\cdot}2H_2O$, the determination of its structure has been beyond the scope of X-ray technique. I am working on its structure as given by the *N* pattern here obtained.

This work has been conducted under the direction of Dr. Ichirô Iitaká.

Magnetization of Matter by Light

ONE of us (F. E.) has shown that small particles of matter of different chemical elements, but of the same physical qualities, irradiated by concentrated light, move in a homogeneous magnetic field, some of them toward the north, some toward the south pole (magnetrode). Therefore, there must be a preponderance of either north or south magnetism on each of those irradiated particles, and they behave like single magnetic poles (charges)[1]. Further, experiment led to the conclusion[2] that, in addition to the oscillating electric and magnetic vectors, light beams must have electric stationary components in the direction of the wave front normal, and that consequently there must be stationary electric potential differences between different points along the beam; and that there must be also a stationary magnetic field in the beam of light with potential differences. Hence, the light beam must have a magnetizing effect, and the charge of a magnet should be changed by light.

Examination of the literature by the other of us (L. B.) showed that even before the time of Oerstedt's experiments, Domenico Morichini[3] (1812) magnetized compass needles by means of the ultra-violet portion of the spectrum of sunlight as used by Herschel. His experiments were verified by M. Sommerville[4], F. Zantedeschi[5], V. Baumgartner[6] and others.

We therefore undertook to test the photomagnetic effect also on larger bodies in continuation of the above-mentioned fundamental experiments on submicroscopic bodies (magneto-photophoresis), through which the general magnetization of the elements and the existence of magnetic 'currents' was brought to light. The experiments were successful with the simplest apparatus, undertaken in a private apartment with a 10 cent compass needle from Woolworths as indicator, and using a beam of light rich in ultraviolet radiation (Hanovia mercury arc, Mazda G.E. daylight bulb) which was concentrated by means of quartz lenses (Hanovia, Zeiss).

Magnetic poles (charges) were induced in various non-magnetic and annealed pieces of iron (paperclips, nails, little iron rods), which were placed perpendicularly to the geomagnetic field, by irradiation for periods varying from minutes to several hours. Those poles were mainly north magnetic and were still present in many specimens after several days.

After short periods of irradiation, it could be shown that the effect was local and on the surface. After long irradiation periods saturation values were obtained.

We also convinced ourselves by means of an amplifier and oscillograph of the Amplifier Company of America that the characteristic of an induction coil with an iron core changed under ultra-violet irradiation.

Naturally, the magnetization was also dependent upon the material, its surface and history to a very high degree. Further investigations are in process.

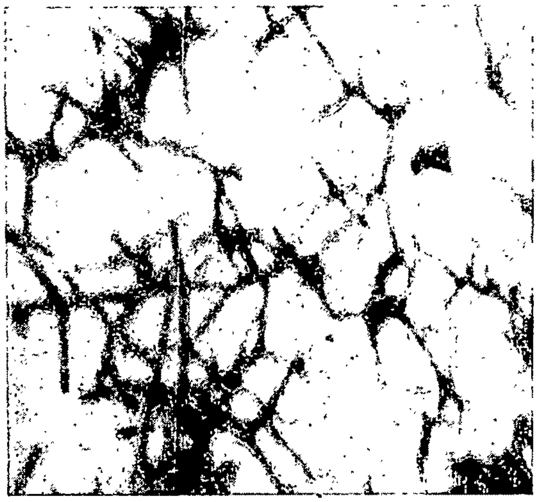
Zinc Oxide Smoke

IN NATURE of December 21, 1940, p. 807, Mr. Fordham has referred to the shape of the particles of zinc oxide smoke, formed by burning zinc in air, as inferred from both optical and electron diffraction data. The accompanying photograph, obtained in this Laboratory by means of the electron microscope[1], confirms his statement that some of the particles are in the form of needles. The photograph shows that the small crystals of which the smoke consists are about 4,500 A. in length and not more than 450 A. in thickness. There is a remarkable uniformity in the apparent length of the crystals, although there is no reason to suppose that they all lie in one plane.



Zinc Oxide Smoke × 23,000

In the electron microscope we seem to have an instrument capable of yielding interesting information about the shape and size of smoke particles.

Weighing Living Marine Animals

I WAS interested in Dr. Gohar's recent communication on this subject[1].

Living marine animals were weighed by me some years ago and I am actively engaged in this work at Plymouth. The work has been interrupted by the War, and since I am teaching at Rugby I can devote the vacations to it only.

However, the accompanying figures were obtained for the common crab, *Cancer pagurus*, last vacation.

	Width of carapace in cm.	Weight in gm.	Volume in ml.	Density	Sinking factor	Percentage error by direct weighing
Male	10·13	145·08	126·77	1·1445	1112	+3·0
Male	10·5	174·01	142·50	1·2211	1187	+2·5
Male	15·5	630·64	498·58	1·2648	1230	+0·98
Female	11·21	185·53	165·01	1·1243	1091	+2·5

I left all the crabs alive in the aquarium.

By the term *sinking factor* one means the density of the living animal divided by the density of its environment, and to remove decimals the number is multiplied by 1,000.

After the crabs had been weighed accurately they were taken from the sea-water and drained for a minute. They were then transferred to a counterpoised clock-glass and weighed directly.

Though this has been the normal way of weighing a crab before the displacement method was devised, it is clear that with a small crab an error of 3 per cent may occur. With large crabs the percentage error naturally becomes smaller.

Though the work is only in its infancy a great many determinations of a similar character have been made on other animals. The method was fully discussed at a meeting of the Linnean Society and published[2]. A short account was also published in NATURE[3]. This work is being carried on with the aid of a valuable Government grant from the Royal Society and also help from the British Association and the Marine Biological Association.

Actually, Dr. Gohar's method was considered some years ago and discarded on account of the difficulties due to osmosis, since if one either dilutes or concentrates the sea-water one brings about considerable changes in the osmotic pressure of the environment, and one needs scarcely point out that changes in the osmotic pressure of the environment may have very far-reaching effects on the weight, volume, and hence the density of the animal.

This difficulty could be partly overcome by weighing the animal first in sea-water and then in an isotonic solution of sodium nitrate and calcium nitrate.

The displacement method is, however, far more accurate and straightforward and the question of osmosis does not occur, except that the osmotic pressure of the environment must be determined before the experiment.

In a good deal of the work I have had the cooperation of Dr. N. K. Panikkar, while together we have recently weighed a living lobster just after moulting, and determined the osmotic changes which occur and also the alteration in weight, and finally the percentage of water in a young lobster both before and after moulting.

A young dogfish is also being kept alive, and its weight and volume, density, sinking factor, and length noted each vacation.

Science and Government

MR. FINLAY's letter in NATURE of January 25 reminds us that it is becoming the fashion in some quarters to claim for men of science special qualifications for administration in everyday affairs. This claim seems usually to be based on (*a*) the acknowledged power of the scientific method to demonstrate truth, and (*b*) the readiness of the man of science to accept truth so demonstrated.

Unrestricted experiment, which is a major feature of the scientific method, renders that method inapplicable in most of our everyday affairs; the well-being of a community cannot be hazarded by an experiment of which the outcome is not a foregone conclusion. Deprived of the discipline imposed by the power of the scientific method, can the scientist rely on his admittedly high professional integrity? Is not this professional integrity a tribute to the compelling power of the scientific method, rather than to the personal integrity of individual men of science? Is there any evidence that in ordinary everyday affairs the man of science differs from his fellows in the degree to which he is a prey to prejudice, obstinacy, and the other common human failings?

If we are deprived of experiment we must fall back on experience, that is, appeal to authority, which is admittedly less satisfying than scientific demonstration; and we cannot, as men of science lacking our chief weapon, expect to prevail in conflict with authority. We are fortunately able to examine a case of organized scientists studying a 'worldly' problem. In 1938 a committee of the Association of Scientific Workers produced a memorandum on the finance of research, being largely a plea for great expansion of research on the grounds that great profit would result. Unfortunately, the committee admitted that neither costs nor benefits of research are measurable, thereby denying the applicability of the scientific method. The memorandum was, therefore, much open to criticism, and finding itself in conflict with authority (the Department of Scientific and Industrial Research), inevitably succumbed.

If there is reason to suppose that scientific workers are not playing their full part in administration, the remedy seems to be that they should enter more fully into 'worldly' responsibilities and arm themselves with authority. There is no new principle, no breaking of tradition, in this; the purest scientist, most impatient of social restraint, is accustomed to publishing his work, thereby voluntarily taking cognisance of society. It is illogical, and therefore unscientific, thereafter to ignore society.

Finally, may I express complete agreement with the article on the cultural significance of science, in NATURE of December 28, 1940? If, by science teaching, we can produce a community schooled to logical and critical thinking, the problem of leadership may well solve itself. An unworthy candidate would less easily pass muster, while men of self-respect might be less reluctant to submit themselves as candidates. Is it too much to hope that some day we shall regard a School Certificate, with credit in mathematics and an exact science, as a minimum qualification for Parliamentary franchise?

169 Hinton Way,
Cambridge.

MAY I be permitted as one of those who were expected to "render their own experience available for the vital task of foreseeing the threats to [the] great heritage of freedom and integrity of thought"[1], to express my view and apprehension concerning the current discussion in these columns about planning, freedom, and science. I think the communication of V. B. Wigglesworth[2] rightly points out that "scientists are human", and not better prepared for leading political positions than other people, and really the dispute about the motivations under which men of science work, or should have to work, shows most clearly that men of science themselves are often exponents of current political opinions, and the authority of 'science', called to witness, is only a fictitious one. With this in view the question whether freedom is in danger if men of science interfere in problems of government is very important indeed, and perhaps a retrospect on similar trends in Germany and Austria, about ten years ago, would not be without interest.

It is quite natural that planning, which is the demand of the hour, finds its strongest advocates among men of science. However, in my opinion a special cause of the decline of the democratic regimes in Central Europe was the ideology of the planned state, the *Stände-staat* (state of estates), which found its best supporters among the scientifically educated intelligentsia. So far as I know the study of this ideology, which was developed especially by Prof. O. Spann[3] in Vienna, and its great influence on the students in universities and technical colleges, has been neglected in the English sociological literature (for example, Mannheim in his book[4] does not mention them), although only by this knowledge can a true understanding of the ideas of the so-called educated people during the rise of fascism be attained, and similar mistakes in the existing democracies prevented. The exponents of the idea of the *Stände-staat* were the scientific experts, the men with a specialized scientific education. Fascinated by planning, and eager to find a secure place in a new hierarchy of society, those men paved, often unaware of the consequences, the way for fascism. Scientific experts are by the whole structure of their present one-sided education easily inclined to become exponents of planning merely for the sake of planning, to follow authoritarian creeds, and so to open the way for political powers which bring in peril not only political freedom, but the freedom of science itself. I cannot help feeling that the political claim of men of science for 'science' in Great Britain and in the United States involves the same idea of organizing 'science' as a special estate, a form of political organization which is incompatible with democracy, and which may become a danger to it.

To propose that men of science should desist from any public activity would certainly be to take a short view. The way of propaganda, however, proposed as a means of enlightening the people about their real benefactors seems only to open the door for pseudo-science, on which ground very strange ideas might develop. Is there no other way open to men of science than to become politicians, no direct approach to help humanity and to bring about the much-quoted new and better world? Of course, there is one, namely co-operation with a liberal and humane educational work, the supreme task of the longed-for state of liberty *and* planning. Here is a task especially for the pure scientists in universities, who, I am afraid, in the existing democracies neglect this part of their professional work, as have done the democratic professor-specialists in the German universities.

RESEARCH ITEMS

Celtic Linch Pin

A FINE enamelled linch pin, British work of the early first century of our era, which was found at King's Langley, Hertfordshire, in 1937, has now been added to the British Museum collections. It is figured and described in *Brit. Mus. Quarterly*, 14, 4 (1940). It is 5·1 inches in length and has a shank of iron with bronze terminal mounts. That on the head is a splendid crescentic ornament inlaid with a red enamel. The pin itself has a creamy-green putina. The scroll pattern of the field is conventionalized almost to the ultimate stage of transformation into geometric, but this in no way detracts from the fluent gracefulness of Celtic art. The contained design is exactly adjusted to the sweeping contour of the head. What is at first sight a central circular medallion is really the spiraliform volute of a scroll, with asymmetric manipulation of detail to give the effect of a fold-over symmetry—an achievement in which Celtic artists took special delight. This is illustrated in a number of pieces of about the same date, one of the most notable examples being the Desborough Mirror, also in the Museum collections. The linch pin recently has been described as "a late and eccentric version of the type that was introduced into Yorkshire by the Parisii in the mid-third century B.C."

A Classification of Birds

THE earlier edition of his revision of the "Classification of the Birds of the World" (1934) having become exhausted, Alexander Wetmore has published a new edition (*Smiths. Misc. Coll.*, **99**, No. 7; 1940). There are relatively few changes in the new grouping: the fossil forms Baptornis and Apatornis have had special families allocated to them, and among the Anseres is included a new family, Paranyrocidæ, for a fossil from the Lower Miocene of South Dakota. Instead of associating the osprey Pandion with the Cathartæ, as L. V. Compton suggested, Wetmore follows the more conservative plan of placing Pandionidæ in the superfamily Falconoidea, considering that the resemblances between the ospreys and New World vultures, upon which Compton placed emphasis, are more likely due to convergence than to genetic relationship.

Geographical Distribution of Opalinid Infusorians

IN his latest study of the opalinid ciliate infusorians, which revises and extends a previous U.S. National Museum Bulletin on the group, Maynard M. Metcalf describes thirty new species and sub-species, and traces with high probability the course of the evolution of the family, unifying facts derived from comparative anatomy, development and geographical distribution in proving "the phylogeny beyond reasonable doubt" (*Proc. U.S. Nat. Mus.*, **87**, 465–634; 1940). In addition, he sets an example to the specialist by deriving from his detailed studies information of great general interest. Thus he has plotted on maps the distribution of different opalinid genera and species, and has associated this knowledge with the distribution of their hosts in an effort to trace the places of origin, the times of origin, and the routes by which hosts and parasites arrived at their present-day dispersal. The general result is that the data derived from opalinids and anurans fit harmoniously with the hypotheses of palæocartographers, such as Arldt and Schuchert, regarding the relationships of land masses in the past, the only discrepancy being that the opalinid facts seem to demand a connexion between Asia-Malaysia and Lemuria during the Jurassic or early Cretaceous periods. The author concludes that the Pleistocene glacial period came too late to be of much significance in connexion with the evolution and distribution of the Anura and their opalinids, most of the evolution of both having taken place long before Pleistocene times.

New Zealand Dobson-fly

AVICE HAMILTON has recently described the life-cycle of the common New Zealand Dobson-fly (*Archichauliodes diversus* Walk) (*New Zealand J. Sci. and Tech.*, 23, A; 1940). This insect, it may be added, is the only member of the suborder Megaloptera in New Zealand and is closely related to the single Australian species *A. guttiferus*. The eggs are deposited in irregular masses on rocks and trees that overhang streams, and the incubation period is about 30 days. The larva is aquatic and each of its first eight abdominal segments bears a pair of unsegmental conical filaments containing branched tracheæ. These filaments are evidently gills, and respiration is stated mainly to be effected by diffusion through their cuticular covering. There are in addition ten pairs of spiracles, but whether these are functional or not is unstated. The food of the larvæ consists mainly of the nymphs of may-flies that are plentiful in the streams that they inhabit. Both prepupal and pupal instars are described. The imago, which is a relatively large insect, lives only six to ten days and has not been observed to feed. The species occurs commonly throughout the country and is often abundant in localized areas. The larvæ serve as food for trout and other freshwater fish.

Soils and Afforestation

AT the request of the Forestry Commission, Muir and Frazer have carried out a soil and vegetation survey of an area of diverse geology some forty miles to the north-west of Aberdeen, which is undergoing afforestation. With the aid of H. M. Steven the results of this investigation have been presented (*Trans. Roy. Soc. Edin.*, **60**, No. 8; 1940), in association with a statement of the current views, on the basis of the Commission's experience, on the choice of tree species suitable for planting on the different soil types in the given climatic conditions. Soils of the podzol group are represented, derived in general from the more acid (geologically) parent materials; the basic igneous rocks give usually soils of the 'brown earth' type. No correlation is observed between the depth of the bleached horizon of the podzols and the rainfall. Grassland is the more frequent vegetation in the 'brown earth' soils; but in the district generally heath and moorland types prevail, dry heath on the acid soils, wet heath and moorland on the soils derived from the heavier basic rock materials.

Inversions in Tradescantia

C. R. SWANSON (*Genetics*, **25**, 438–465; 1940) has shown that a hybrid population of Tradescantia resulting from the natural hybrids of *T. canaliculata* and *T. humilis* contains a considerable number of inversions in the chromosomes. There is a high correlation between number of interstitial chiasmata and number of inversions. This is taken as evidence that interstitial inversions are numerous but are usually undetected where the chiasma-frequency is low and localized. With hybridity, genes controlling pairing at meiosis recombine and may induce pairing of parts of chromosomes which otherwise were isolated. Pairing in chromosomes of Tradescantia begins at the distal end of the chromosomes. The phylogenetical aspects of the data are discussed and it is shown that self-incompatibility favours gene recombination, while inversions and chiasma localization act as barriers to recombination. Where self-sterility genes lie close to inversions they tend to aid the perpetuation of inversion heterozygosity.

Spontaneous Chromosome Change

C. D. Darlington and M. B. Upcott (*J. Genetics*, **41**, 297–328; 1941) have analysed spontaneous structural alterations in the chromosomes of Tulipa Hyacinthus and Tradescantia. In many respects these changes are similar to those induced by X-ray radiation. It is therefore possible to discuss the reasons for the diversity of the results of such changes. For example, the frequent occurrence of small acentric rings, attributed to two breaks initiated by one hit, are more probably the result of two breaks followed by preferential union between non-sister chromatids. Similarly it is probable that the diverse results of induced exchange are due to the diversity in the conditions of reunion. Further, reunions between broken ends of sister chromatids and sometimes between non-sister chromatids may take place many cell generations after breakage. The experimental dosage frequency of changes and fractionation effects are therefore interpreted by the competition in types of reunion and not by the frequency of types of break initiated by a hit. The authors also point out that the new interpretation emphasizes that chromosome splitting is uniform and takes place late in the intermitotic resting stage.

Thermal Conductivity of Rocks

KNOWLEDGE of the thermal conductivity of the materials of the earth's crust and its dependence upon temperature is required for the quantitative treatment of numerous problems of geology and geophysics. F. Birch and H. Clark (*Amer. J. Sci.*, **238**, 529; 1940) describe an apparatus for the measurement of conductivity between 0° and 500° C. and present results for 18 igneous rocks, 7 sedimentary and metamorphic rocks, 3 single crystals and 4 glasses. At 0° C. the conductivities of all of the rocks lie between 0·014 and 0·004 in C.G.S. units; at 200° C. all lie between 0·009 and 0·004. The conductivities of the poorest conductors, the felspar aggregates and the glasses, increase with temperature, whereas those of all the other crystalline materials decrease. The highest conductivities are found for the ultrabasic rocks, hitherto unstudied, but here, as with other rocks, the variation is such that the values tend to converge as the temperature increases. While the differences are important at the temperatures at which measurements of geothermal gradients are made, they become much less so at depths within the crust of the order 10–20 km. A simple method of computation permits a calculation of the conductivity of fresh igneous rocks in terms of their mineral composition with an error usually less than five per cent at temperatures up to 200° C. This method may prove useful in the discussion of gradients and heat flow in rocks the conductivities of which have not been measured. An interesting example is a gradient of 144–170 metres/° C. in a Russian occurrence of pyroxenite and peridotite; from this the heat flow may be estimated at about $0{\cdot}8 \times 10^{-6}$ cal./cm./sec., in fair agreement with the results of Benfield in Britain and Bullard in South Africa.

Stereochemical Types and Valency Groups

THE Bakerian Lecture by N. V. Sidgwick and H. M. Powell (*Proc. Roy. Soc.*, A, **176**, 153–180; 1940) deals with stereochemical types and valency groups, and illustrates the advantages of having alternative ways of grouping the same set of facts. Experiments on X-ray and electron diffraction, absorption and Raman spectra, optical activity and electrical dipole moment have produced data of interest to both physicist and chemist. So far, the treatment of the results in theoretical physics has linked up the stereochemistry of the molecule with the number of shared and unshared electrons in the polyvalent atom, and the electronic sub-groups which these occupy. Unfortunately for the chemist, when the energy differences between the various possible electronic arrangements, or between various stereochemical groupings which are compatible with the same electronic structure, are small, they cannot be determined by calculation. Thus, possible instead of actual arrangements are predicted. Furthermore, the chemist cannot always tell whether the bands in a given molecule are *s*, *p*, or *d*, even when this is clear to the physicist. An attempt is therefore made to relate the data to some property of the molecule with which the chemist is more familiar. The arrangements in space of the covalencies of a polyvalent atom, while they are subject to small variations, seldom exceeding 5° or 10°, tend to conform to quite a limited number of types. By using the size (in G. N. Lewis's sense) of the valency group of the central atom, and the number of shared electrons which it contains, together with that of the preceding (unshared) electronic group in the atom, the authors are able to fit the experimental results into eight relationships (see NATURE, July 13, 1940, p. 70). The bibliography at the end of the paper covers fifteen pages.

Flame Spectrum of Carbon Monoxide

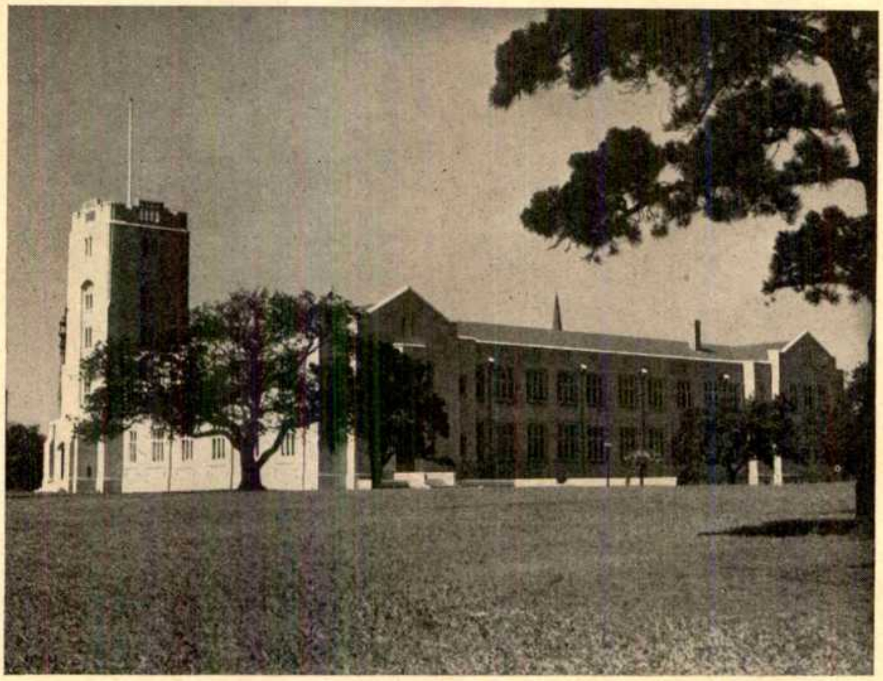
APART from the complexity of the spectrum of the flame of carbon monoxide burning in air or oxygen, great difficulty has been found in interpretation because of the weakness of the bands relative to the continuous background. The results of an improved technique have been reported recently by A. G. Gaydon (*Proc. Roy. Soc.*, A, **176**, 505–21; 1940). Whereas previous workers had used relatively fast photographic plates with low contrast, plates of the highest contrast were used in the present investigation. The improvement in contrast has enabled new measurements of the spectrum to be made, and the structure of the band system and its origin are dealt with in the light of the more recent developments in knowledge of molecular structure.

THE AUSTRALIAN NATIONAL STANDARDS LABORATORY

BY SIR DAVID RIVETT, K.C.M.G.

COMMONWEALTH COUNCIL FOR SCIENTIFIC AND INDUSTRIAL RESEARCH

WITH the help of the Department of Scientific and Industrial Research, a plan for a Standards Laboratory in Australia was drawn up in 1927, to be controlled by the recently created Council for Scientific and Industrial Research. Unfortunately, the need for it was not fully realized in political circles until, after ten years or more, the growth of secondary industries and an impending acceleration due to war activity, made further postponement obviously dangerous.



AUSTRALIAN NATIONAL STANDARDS LABORATORY, SYDNEY

Rapid progress has been made in the past eighteen months and a handsome building has now been completed on a site generously provided in its grounds by the University of Sydney. The front (eastern) elevation is faced with white Hawkesbury sandstone to fit in with the general architectural scheme of the main frontage of the University; the sides and back are treated with light-coloured brick and stone trimmings.

With two stories and a basement in front and three stories and basement behind, the total floor space available is 80,000 sq. ft. Besides laboratories and test rooms for the usual three sections of metrology, electro-technology and physics, there is adequate provision for general offices, workshops and a library. Many of the rooms, including a 130-ft. tape tunnel, are air-conditioned, the plant being designed to maintain a temperature of 68° F. ± 1° at bench height.

Particular attention has been paid to the problem of means to run special electrical or other services from one room to another. Vertical ducts to every alternate room and horizontal ducts along the external walls serve this purpose. In addition, numbers of 2-in. diameter pipes have been embedded in the reinforced concrete floors to provide passage between rooms on opposite sides of corridors.

The laboratory will hold all national standards for the Commonwealth and will, of course, maintain intimate contact with the National Physical Laboratory at Teddington, which during the past two years has extended its hospitality to some nine officers for purposes of general experience in the calibration and use of instruments. It is the intention to establish substandards laboratories, under State Government control, in certain of the capital cities, to carry testing work beyond the stage to which it will be taken by the National Standards Laboratory.

Considering existing difficulties in obtaining equipment, the Council has been fortunate in securing the instruments and workshop machines which are now in its possession.

The building, which cost £100,000, will for the present house certain other activities of the Council for Scientific and Industrial Research in physics, as well as the normal standards services.

COLOUR TOLERANCE

ON February 12, the Physical Society Colour Group held its inaugural meeting at the Regent Street Polytechnic, London. In accepting the responsibility for the formation of this group, the Physical Society hopes to provide a valuable opportunity for people interested in colour, whether as physicists, chemists, dyers, industrialists or otherwise, to meet for their mutual benefit. A number of societies have already agreed to co-operate by becoming founder societies of the group and, in addition to the Physical Society, these include the British Kinematograph Society, the Illuminating Engineering Society, the Institute of Physics, the Royal Photographic Society, the Society of Glass Technology, the Society of Dyers and Colourists, and the Oil and Colour Chemists' Association.

The opening meeting was in part occupied by a discussion of the constitution of the Group, but when this had been formally adopted, a discussion on "Colour Tolerance" was held. Such a subject presents a very wide field, and was chosen intentionally for the opening meeting so as to interest as many people as possible and to provide an opportunity for each type of worker to become acquainted with the others.

In a brief introduction, it was shown that the problems of colour tolerance can be divided roughly into three, namely, the commercial aspect, in which the requirements of the customer have to be considered, the technical aspect, in which the limitations of manufacturing processes have to be taken into account, and the physical aspect, in which the specification and measurement of colour tolerances must be discussed.

Mr. R. F. Wilson, of the British Colour Council, in dealing with the commercial side of the problem, showed how valuable it is to limit the number of colours employed in any particular industry to the minimum that will satisfy the general public. In this way manufacturing costs can be very materially reduced and the irritating task of trying to differentiate between colours that in fact possess only minute differences, can be avoided. Remarkable figures for the number of colours that were used until recently in various cases, as, for example, in stockings and in the dyeing of the soles of ladies' shoes, were quoted during the discussion. Mr. Wilson also referred to the importance of the lighting on the accuracy to which colours can be matched, and appealed for more uniform lighting conditions. He instanced the case of a firm that has an excellently equipped viewing room and yet often encounters difficulties because the very perfection of its lighting arrangements is so different from that employed by the retailer. The question of a standard daylight lamp was raised by several speakers, while it was also pointed out that for many purposes, of which theatre lighting and interior decoration may be cited, artificial lighting is more important, so that a standard artificial lamp is also very desirable.

A point raised by Mr. Wilson and echoed by other speakers was the often serious trouble that arises when persons with defective colour vision are employed in colour industries. Colour-blindness may be regarded as a somewhat extreme case; but it is evident that even slightly abnormal vision may affect the ability of an observer to detect small colour differences correctly.

Mr. H. W. Ellis, of the Clayton Aniline Co., dealt with the technical limitations of dyeing processes and in his paper he demonstrated how the limits to which the dyer should be asked to work ought to be determined very closely by the purpose to which a dyed material is to be put. A material may sometimes have to be made fast to light, sometimes to washing, sometimes to the effects of perspiration and so on, but only in exceptional cases would the expense of using a dye fast under all conditions be justified. Thus while curtain material should be fast to light, this is of little importance in the case of ladies' underwear, which must, however, be made fast to washing.

Again, it may happen that the colour of a surface varies according to the direction in which it is viewed, and when several different viewing angles are presented simultaneously, as for example with hats, it becomes important that the change in colour with angle should be held within close limits. Samples were also shown to demonstrate the change in colour that results with given changes in the chemical conditions of dyeing; but perhaps the most striking feature of Mr. Ellis's paper was the evidence it afforded that tolerance questions may arise in many and varied forms.

Mr. J. W. Perry, of Messrs. Adam Hilger, Ltd., had the task of discussing the physical aspect of colour tolerances. He indicated how tolerances can be expressed in the standard C.I.E. chart or, if desired, on an oblique projection of the chart known as the rectangular uniform chromaticity scale (R.U.C.S.), and then developed equations from which the tolerance, defined initially in terms of the additive primaries of the C.I.E. system, can be transformed into the terms of the subtractive primaries of the dyer. One of the greatest difficulties, and one of the greatest opportunities, for the Colour Group, will be to bridge the gap between the additive colour mixture familiar to the physicist and the subtractive colour mixture always employed by the dyer. This is unfortunately a by no means simple matter and it has the, to the dyer, added disadvantage of requiring a fair amount of mathematics. Mr. Perry did not spare the chemists and dyers, and later in the meeting urged that each member of the Group should be prepared to make the mental effort required to understand the approach of other members to the problems of colour. At the same time, those taking part in the discussion must bear in mind that many of their audience have been trained along very different lines from their own and they, too, should make an effort to express themselves in the simplest possible manner.

It was inevitable that at the opening meeting a number of points would arise that had little direct bearing on colour tolerance, and it was especially interesting to notice how frequently references to colour-blindness occurred, suggestions being made that a test for colour-blindness should be instituted in schools. The effect of eyestrain when using instruments, the sensitivity of the unaided eye in detecting small colour differences compared with the sensitivity when a colorimeter is employed, the mathematical developments of colorimetry in the United States, the merits of spectrophotometers, all came in for some comment. The excellent attendance, the interest of the members and the wealth of material as subjects for discussion, augur well for the future of the Group.

ELECTRICALLY DRIVEN SHIPS

In war-time, while the question of capital cost is not the most important consideration, anything which increases the tonnage of the Navy and of the merchant fleet deserves serious attention. During the War of 1914–18, the attempts of the German Navy to blockade the British Isles by the unrestricted use of the submarine presented a similar problem. It was solved by the adoption of entirely novel methods. In addition to methods of speeding up ships of conventional design, the so-called 'fabricated' ship was constructed, and bridge builders and constructional engineers were called in to help. The parts of the hull were constructed, usually inland, and were sent to a convenient location on the coast where they were erected and launched.

In the *Electrical Review* of January 24, Mr. A. Regnauld makes a useful contribution to the solution of the problem by pointing out that ships' output can be increased by increasing their speed. This can be done by utilizing the large available electrical manufacturing industry for the production of the propelling machinery, and leaving the shipyards to deal with the production of the hulls.

In present circumstances, the manufacture of electric generating equipment is largely in abeyance and so also is the production of prime movers. If the shipyards could increase the output of hulls, the propelling equipment for the additional vessels could be constructed in its entirety by the electrical manufacturers and associated boiler manufacturers when steam turbines are installed. In all modern turbo-driven steamships, some form of speed-reducing gearing must be employed. The most efficient propeller speed for merchant tonnage, namely, 12–15 knots, is 100–120 r.p.m. The economic speed of the steam turbine is very high, somewhere about 3,000 r.p.m., varying according to size. Neither the turbine nor the heavy-oil engine can be readily reversed. This involves the use of specially constructed turbines running in the reverse direction to the main turbines. These astern turbines are often of sufficient size to develop more than 50 per cent of the ahead power. They may only be required for half an hour or so, at the beginning and end of a voyage when manœuvring out of and into port. This represents a very uneconomical effect.

With the electric drive, particularly if two or more generators are employed to supply the maximum power, a very high degree of flexibility is obtained at all the different speeds used in service. If bridge control be fitted, it would prove of supreme value in any emergency which might arise. The maintenance charges comprised of overhauls and repairs are generally in favour of the electrically driven ship.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Saturday, March 8

Society for Cultural Relations with the U.S.S.R. (at the Royal Hotel, Woburn Place, London, W.C.1), at 1 p.m.—Prof. George Thomson: "Anthropological Theory in the U.S.S.R."

Monday, March 10

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 5 p.m.—Mr. Gerald Seligman: "The Structure of a Temperate Glacier".

Tuesday, March 11

Chemical Engineering Group in conjunction with the Institution of Chemical Engineers (Joint Meeting) (in the Rooms of the Chemical Society, Burlington House, Piccadilly, London, W.1.), at 2.30 p.m.—Mr. E. W. Murray: "Ventilation (Natural and Artificial) in relation to the Blackout".

Illuminating Engineering Society (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 2.30 p.m.—Addresses on "Recent Work on A.R.P. Lighting Problems."

Wednesday, March 12

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Annual Meeting. Prof. P. G. H. Boswell, F.R.S.: Presidential Address—Part 1: "The Status of Geology, a Review of Present Conditions"; Part 2: "The Stability of Minerals in Sedimentary Rocks".

Friday, March 14

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1.) at 3 p.m. Annual General Meeting. Professor H. C. Plummer, F.R.S.: "The History of the Vertical Telescope."

North-East Coast Institution of Engineers and Shipbuilders (in the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Mr. J. Calderwood: "Some General Observations on Vibration".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer for Mechanical Engineering Subjects—The Secretary, Northampton Polytechnic, St. John Street, London, E.C.1 (March 17).

Demonstrator in Biology—The Principal, Technical College, Kingston-upon-Thames.

Assistant Professor of Metallurgy—The Director, Department of Mining and Metallurgical Engineering, Laval University, Quebec City, Canada.

POPULATION PROBLEMS AND EDUCATIONAL POLICY

UNDER present conditions in the Western World we are faced with a decline in the population which shows every sign of attaining serious dimensions over the coming decades, a decline unparalleled by anything that has happened in human history before. The decline will be most strongly felt in Scandinavian countries, in the white portions of the British Empire, among other nations of Western Europe, and in the United States ; but there is every indication that as time goes on it will extend to all parts of the earth. affecting every race and colour. Opinion may be divided over the immediate causes which have led to the fall in the birth-rate below replacement level. It is significant, however, that it has come about first among those nations which have been foremost in the discovery and application of science. It is significant, too, that the decrease in births has occurred in countries where living standards are higher than elsewhere, so that it can have no relation to the problem of mere survival in any Malthusian sense, and its explanation must be sought in the complex of economic organization and personal ideals which help to make up the present social order.

This decline in the reproduction rate of certain peoples is not without its tragedies. In recent years, for example, the Jews in Central Europe have been limiting their births more severely than the nations among whom they have been living. With whatever eyes we may look upon the persecutions and indignities to which they have been subjected, and the efforts made to transport them from one place to another, if left in peace their numbers would have shown a marked falling off even in a generation's time, and the decline might well have been progressive. Similarly, as we watch and take part in the magnificent fight which the British Empire is putting up against the Totalitarian Powers, we cannot escape the realization that in a few decades' time, the democratic nations will be considerably weaker in effective man-power than they are now. Victory will have been dearly bought if its fruits sink below a rising tide of superior numbers in other parts of the world. If the British people are to continue as a world power, in any sense of the term, it is imperative that a positive demographic policy should be put into practice, and soon rather than late.

Nor are the problems which a declining birth-rate brings upon us restricted to the international field. Great and almost more pressing ones face us at home. It was among the wealthier classes that the practice of family limitation first came to be adopted. This may prove to be a temporary phase ; but while it continues it results in a situation in which the greater part of the next generation is recruited from the lower strata of society, and from those who with the largest families have the greatest struggle to provide the barest essentials of life in the form of food, nursing care and house room. Whether such a state of affairs will lead to any disgenic results, and so produce another type of national decline, is still a moot point. From the pioneer work of M'Gonigle, Orr, and now of many others, it is abundantly clear that the poorer sections of the community, even in normal times of peace, if members of families with several dependants, are cramped in their health and physical development, not to mention those intellectual and cultural influences which civilization should confer. To see that such people receive sufficient for their full physical development would not be an increased burden, but a wise and beneficial investment, which would reveal itself in the improved effectiveness of the nation, whether on the battlefield, in the factory or in the home. Alternatively, the wealthier and professional classes, with more house room and easier standards of life, are not reproducing their numbers; they are not, therefore, bearing their full share in the production of the future British nation, which their higher living standards, their richer cultural environment, and, in some cases at any rate, their superior intellectual endowments should lead us to expect.

Here we are face to face with the crux of the whole problem. At the present time, parents of the wealthier classes have stronger inducements to restrict their families than any other section of the community. They live in an environment in which child-bearing is unpopular, nursing and medical care is expensive; the parent has to see his child through long years at preparatory and public schools, and then at the university, before finally having to produce the capital to see his son launched successfully on a professional or business career. On a proportionate but lower scale the cost of producing and educating daughters is also formidable. While such a state of affairs continues—and it is not easy to visualize any early remedy—the idea of a small family will be extremely difficult to overcome, and since social codes spread from above downwards, it seems likely to affect all grades of society until a considerable amount of social reconstruction has been carried through.

At this stage in the demographic progress of the nation it is interesting but disquieting to observe how acquiescent public opinion and even our intellectual and political leaders are in a situation which, if left to itself, may develop into a national calamity. The reason for this cannot be due to lack of information, for the facts as outlined above have been available for some time past to all readers. The prevailing impression appears to be that some fall in the population of Great Britain would be welcome, and that in the long run things will right themselves. One or two economists have directed attention to the prospects of decreasing markets, and to shifts in consumer demand, but their discussions have borne the impression of being mainly theoretical and of no immediate moment. On the other hand, signs of a change in social emphasis are beginning to appear. The scheme for cheaper milk to children and mothers, under which in certain circumstances it can be provided free, although introduced to alleviate the severity of war-time rationing, is a step in the right direction. A more considerable one would be the introduction of a national scheme of family allowances, particularly if its scales were made elastic enough to cover all social grades. Support for the idea of family allowances is growing perceptibly at the present time, but the Government has announced in the House of Lords that the Government cannot find the necessary funds for such a scheme during the War. Curiously enough, opposition to family allowances comes more from the ranks of organized labour, where their effect would be most beneficial, than from those who would have to bear the extra budgetary cost.

So far, the fall in the child population has passed almost unnoticed by health and education authorities, for it has led to concealed, but none the less real, economies in buildings and staff. It has been among the public schools that the fall in recruitment has begun to show itself in the form of actual financial stringency, as well as in empty boarding houses. Among the public schools the decline in numbers has gone so far, having been aggravated by the War, that the Headmasters' Conference has taken the matter up, and the Board of Education is being sounded to see what assistance may be forthcoming from the State. Since discussions are still proceeding it is impossible to forecast what may emerge. Judging from what has appeared in the Press, there are indications that efforts will be made to retain the boarding-school principle, while extending the scope of entry through some form of public assistance.

All such proposals are purely short-range and empirical in character. Although they may contain the seeds of a genuine demographic policy, they are not looked upon in that light by those who have brought them forward. In fact, we have to realize that demographic problems have not yet reached the arena of practical politics anywhere in the British Empire, whether we are thinking of the white people whose numbers are about to decline, or of the coloured races who, under British rule, are multiplying so rapidly that with them Malthusian conditions actually or very nearly apply. Social distress in the West Indies, in India, too, and empty cradles in Great Britain are complementary evidence that to the great majority of our leaders no demographic problem is thought to exist. Such conditions point to the vast field of social welfare and betterment that is waiting to be taken up.

In approaching this field, however, the only line promising any kind of permanent success lies through education, particularly through the application of those biological principles which may be termed human biology. What is envisaged is a reorientation of social and personal ideals, so that individualism and money standards no longer hold full sway. The public schools, for example, must come in for a good deal of reconstruction. Founded as most of them were when children were plentiful, and when women in consequence were accorded a low status, they have accentuated the separation of the sexes and imposed a monastic mode of life upon the boys as well as upon the staff. Through their character training they have extolled the ideal of masculine individuality. The leadership principle is the antithesis of co-operative work involving all kinds of people and both sexes. From now on, leadership to be at all effective as a social force must involve responsibility for rather more children than with other grades of society. Such questions as these have been elaborated in greater detail in a memorandum on "Human Biology and the Crisis in the Public Schools"[1] issued recently by the Educational Advisory Board of the British Social Hygiene Council. The memorandum merits careful consideration by all who are concerned with the future of the British nation, as well as by those primarily interested in the educational policy of the public schools.

If entry to the public schools is to be widened to maintain numbers, one immediate result may be to intensify the desire in parents to limit their families. To counteract such an influence, in granting its assistance the State should impose conditions calling for reforms in teaching practice and educational aims. For the future it will be necessary to inculcate the idea that girls and women are true partners in life of boys and men, that many of the finest rewards in life, its tenderest emotions and greatest personal satisfactions lie in the home. Sex must be freed from its associations of false sentimentality and furtive pleasures, and made the subject of rational thought and conduct. This should make for greater happiness in providing a more natural framework for human activities and desires, tending to reduce many of the frustrations which now bear so heavily upon society.

In bringing about a new orientation of social standards it is very probable that educational practice will lag behind political expediency, for educational policy is nearly always conservative. The State will have to assume the role of a true parent to its children. To achieve this, the present system of financial rewards in the shape of wages, salaries and profits may need to be modified in keeping with a more co-operative form of community, in which returns bear a closer relation to the biological responsibilities of individual members. As indicated above, a bold scheme of family allowances would make a big difference. Social and economic rearrangements of this nature would not be in any way subversive, for they would make for a stronger and a healthier nation. They would also provide a bulwark for democracy, for once the principle of family limitation is recognized, the task of bearing children is one of the last that public authorities will be able to impose upon private individuals. The true source of democracy is the home, and it is from healthy and well-satisfied homes that the future members of the British nation must eventually come.

THE MYSTERY OF RUST

The Corrosion of Iron and Steel

Being a General Account of the Work of the Corrosion Committee of the Iron and Steel Institute and the British Iron and Steel Federation. By Dr. J. C. Hudson. Pp. xv+319+43 plates. (London: Chapman and Hall, Ltd., 1940.) 18*s*. net.

THE late Sir Robert Hadfield made a hobby of collecting statistics about steel, including the loss caused by corrosion; he mentioned at a time when the world slump was at its height that the destruction due to corrosion that year was probably greater than the total production of new steel. He might well have added, what are we chemists and metallurgists doing about it?

For many years the only remedy was paint: the painting of the Forth Bridge has been described as an eternal circle of operations. When I was a student, G. T. Moody propounded a theory on what happens when iron rusts, which promptly brought forth a rival one from Wyndham Dunstan: engineers were aghast at the temerity of chemists in interfering with the normal happenings of Nature, and were not surprised that the chemists failed to agree. Forty years on, and the bad old times when iron rusted are giving way to the new age of rustless alloys, official committees of investigation, some understanding of the problem, and a considerable amount of first-class research.

It is estimated that the annual cost, including labour, of protecting the iron- and steel-work in

Great Britain amounts to £40 million: in the United States 120 million gallons of paint per annum are applied to ferrous metals. It is obvious that a minute percentage on these bills would provide very large sums for research, and it may be asked why the world is not sufficiently enlightened to-day to insist on such a levy. In the days to come the world will not be able to afford to let iron rust at this rate.

Something, however, is being done, and it is the purpose of Dr. Hudson's book to tell the story of the Corrosion Committee. It was formed in 1928 under the chairmanship of Dr. W. H. Hatfield; it has representatives of producers and scientific workers and the direct support of industry both in kind and through the industrial research laboratories. It is one of those typically British volunteer organizations in which the spur is the love of the cause and the reward is the fact that something has been accomplished. Such a team requires above all leadership, and whether he functions as coach or stroke, Dr. Hatfield has given clear proof that he can provide this. Financial help is provided by the Department of Scientific and Industrial Research, by the Admiralty, Lloyd's and the British Steelworks Association: it is inconceivable that such a cause should be short of the necessary funds. There is similar work in hand abroad, mostly looked after by co-ordinating committees, and the book gives a short note about the activities in six countries, the most important being the United States. Needless to say, there is, or was, close international co-operation in these matters.

An iron plate rusts in a single night by chemical action, the jute fibres of a sandbag are rotted within three weeks in hot weather by bacteriological action: clearly the affinity of iron for oxygen is very great. Any investigation must discover the factors causing rusting and the possibility of their removal. To prevent rusting, both the resistance of iron and steel to rusting and the means of protection against rusting must be improved. These are the essentials of the problem. How are they to be tackled?

The late Prof. H. E. Armstrong tried to train his engineering students on the detective problem, "What happens when iron rusts". Put bluntly, they resented being taught chemistry in this way, being "forced to think" as he said, and wanted to have facts thrown across the lecture table, which they could catch and throw back in the examination. Perhaps engineers have been too ready to accept the fact that iron rusts and adopt a fatalistic attitude to the phenomenon.

The problem of rust must be tackled from the point of view of the shape of things to come, which is week by week being developed in the editorial columns of NATURE. Rusting is as much as anything due to the pollution of the air in our cities: let us therefore have clean air. This can largely be effected by legislation: the people need clean air just as much as iron does. Let us have clean air just as we have clean water: the opposition of the interests who would have us burn raw coal must be swept away. The politicians play with the things the mass mind can grasp, and the big problems that matter are left for the most part to find their own solution in the efflux of time. Surely science can make the mass mind grasp the need for clean air.

Steel can be rendered almost entirely resistant to rusting by suitably altering its composition, but this is costly—too costly in fact for other than special application. Nickel costs £200 a ton, and only 113,000 tons were produced in 1937: there must be more nickel produced at a much lower cost—a monopoly, if there be one, must disappear, for it is not in the public interest.

The book is a general summary of the first ten years' work of the Corrosion Committee and describes it in very readable form. If a reviewer is entitled to skip and turn to the end, as some people do with a detective story, then we may turn to Chapter xi, where what has been accomplished is set out clearly and succinctly.

The positive results fall under two heads. One is the development of low-alloy rust-resisting steels, largely carried out across the Atlantic, which has enabled the resistance of structural steel to rusting to be doubled. The other is a multitude of improvements in painting procedure. Even more important probably is the far greater understanding of the problems, both generally and in detail, which will ensure future progress being much more rapid.

The possibilities of low-alloy steels are immense; their development waits on the elaboration of methods for their fabrication, but these are rapidly forthcoming. Protective coatings of greater durability, involving the use of synthetic plastics as paint components, also promise to give better and cheaper maintenance.

Great progress has been made with special steels for the chemical and oil-refining industries, which must have these and can afford to pay the price for them. Here, as always, there is a race between demand and accomplishment.

Iron rusts in the air, under the ground and in the sea; this is its nature. Man needs bridges in the air, pipes under the earth and ships at sea; he must face the challenge how to make them last longer. In the long run, the effort is one of trained brains, helped by time and money. We can see to it that the training is not lacking and that the right men are given their chance to achieve.

E. F. ARMSTRONG.

EMPIRICISM IN METAPHYSICS

The Nature of the World

An Essay in Phenomenalist Metaphysics. By W. T. Stace. Pp. vii + 262. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1940.) 18*s.* 6*d.* net.

THE book which bears this ambitious title is an essay in metaphysics on a phenomenalist basis. As was to be expected, the course of the inquiry leads the author to discuss most of the problems of philosophy. This fact may perhaps excuse any tardiness in this notice of the work, for it would be a poor compliment to the writer to offer an impression gained after a hasty reading. After two careful readings of this book I can say that, though I still disagree with the method and many of the conclusions, it is in my opinion one of the most important contributions to metaphysics which have appeared in recent years.

Prof. Stace is a thorough-going empiricist, at least in intention. The point where argument would break out is precisely whether the intention has really been fulfilled. Has any material been used in the construction which is not, in the strict sense, derived from experience? It seems to me that there is an *a priori* element in the metaphysical construction, and that it comes in at the place where Leibniz suggested that the *a priori* must be introduced when he added to the formula of empiricism "Nihil in intellectu quod non prius fuerit in sensu," the phrase "nisi intellectus ipse".

However this may be, Prof. Stace conceives the purpose and method of philosophy in a thoroughly empirical and 'scientific' manner. The proper method of philosophy is, in his opinion, that of hypothesis. "An hypothesis is put forward regarding the nature of the concrete. An attempt is then made to show that this hypothesis 'explains' the known facts about the world. Finally, reasons are given why this hypothesis should be preferred to others which equally explain the facts." It should be added, however, that by 'explain' Prof. Stace means very much what science means by it, and not the finding of reasons for things or answers to the question 'why?'. It will be seen that Prof. Stace renounces the kind of insight which many philosophers have sought—one which would grasp the world as a rational whole and would find that in the end reality and value were reconciled.

The central concept of this metaphysical construction is that of the cell. The hypothesis put forward is that the universe is a plurality of cells, all of which are of the same fundamental structure. Nothing exists except cells. Though the metaphysical conception of cells is, of course, suggested by the biological, it has properties which differentiate it from any scientific hypothesis. A metaphysical cell is absolutely indivisible. It is not material nor is it spiritual; it is the concrete reality of which matter and spirit are abstract aspects. Every cell consists of two parts, consciousness and datum, and cells differ in the quantitative and qualitative characters of their data. No doubt the hypothesis thus baldly stated has a paradoxical air, but its working out is calculated to remove the prejudices of common sense.

Naturally, Prof. Stace realizes that his theory has a resemblance to Leibniz's philosophy of monads, and it must be added that one of the most startling of Leibniz's assertions concerning his monads is repeated by Prof. Stace about his cells—they do not interact, they "have no windows". Leibniz felt that the appearance of interaction deserved at least some explanation, and he devised, to meet this need, his famous theory of the "pre-established harmony". Prof. Stace feels no such need; sufficient for him that in fact the cells do so function and develop that they appear to be interacting, that there is "cellular correspondence". It seems to me that other readers as well as myself will consider this cellular correspondence an odd feature of the world for which they would like an explanation, but Prof. Stace would reply that we were searching for what we cannot have—reasons.

It would be interesting to touch upon some more topics on which Prof. Stace has invited argument, He maintains that all consciousness is thinking, and that there is no such thing as will. In order to carry out this hypothesis, he has to employ the notion of "submerged concepts". Again, on the subject of values, he contends that the validity of value judgments and their universality has nothing to do with the "so-called objectivity" of values. This is a discussion which deserves attention.

I cannot think that what Prof. Stace has to say on religion and the reality of God is quite on the level of the rest of his book. He has perhaps not allowed himself sufficient space, and it may be hoped that he will devote a separate volume to the philosophy of religion.

W. R. Matthews.

UTILIZATION OF CHEMICAL LITERATURE

Chemical Productions
Their Nature and Use. By Prof. M. G. Mellon. (International Chemical Series.) Second edition. Pp. xii+284. (New York and London: McGraw-Hill Book Co., Inc., 1940.) 18*s*.

IN spite of the fact that during the last decade there has been an enormous increase in chemical literature, Prof. M. G. Mellon has been able to retain substantially in its original form the classification evolved in the first edition of this work. As the author's desire is to provide a text-book for an undergraduate course in chemical literature, this classification is based rather on the nature of the publication in which the information appears than on the nature of the subject-matter. Thus, in the first place, he divides the literature into publications containing new material or new presentations and discussions of known material, designating these "Original Sources (Unorganised Information)"; publications containing information compiled from an original source arranged according to some definite plan, which he designates "Secondary Sources (Organised Information)".

Under the heading "Original Sources" there are four subdivisions, namely, periodicals, contributions of institutions, literature on patents, and miscellaneous contributions. "Secondary Sources" are subdivided into periodicals and serials, bibliographies, general works of reference and text-books, and miscellaneous compilations.

A separate chapter is devoted to each sub-class, and, apart from general descriptions of each type of chemical literature, a great deal of useful information will be found. For example, lists are given of journals available on general science in the different countries of the world, together with a note of the standard abbreviations used in citing references to the periodicals. In the same way general chemical journals are listed in chronological order of appearance. These include the earliest journals available, and all the more important later ones, the list being of particular interest in that it indicates the length of life of these publications.

Current journals which are mainly devoted to specialized branches of chemistry are classified under the headings used in *Chemical Abstracts*. In this case titles were selected by some one interested in the particular subject, and accordingly the list embodies the more generally useful periodicals classified under thirty different headings.

There are included in the book in addition many valuable suggestions leading to a greater understanding of the potentialities of chemical literature. Whether the student is concerned with patent searches, abstraction of journals, the compilation of bibliographies or some specialized research in the chemical literature, he will find it helpful and time-saving to follow the general principles laid down by the author.

Finally, in order to stimulate actual contact with the publications in question, there are appended a number of study sheets or library problems relevant to certain sections of the book. These, it is suggested, might provide the basis of a practical library course in chemical literature.

CORN GROWING IN THE OLD DAYS

Corn Country
By C. Henry Warren. Pp. viii+136+34 plates. (London: B. T. Batsford, Ltd., 1940.) 10*s*. 6*d*. net.

CORN growing in Great Britain falls roughly into three periods: the open field period from early times up to the end of the eighteenth century; the craftsman period which attained its highest development during the years 1850 to 1880; and the modern period in which science and machinery dominate, and which set in about 1890. The countryside now shows little but vestigial remnants of the open field system, but memories of the craftsman period still linger among the old men, and form part of the background of our village life. Happily, various modern writers have discovered the literary value of English country life, and a considerable number of books are being written about it; some by those who have actually gone through what they describe, such as Fred Kitchen, a farm worker with a natural gift for writing; others by men who have explored farms and villages to note down what they could see and hear.

Mr. Warren's book belongs to this second group: he has succeeded in putting together a very interesting account of the first two periods. For the story of the open fields he has gone back to some of the old records and has reproduced pictures from the well-known Grimani and Louterell psalters.

But the greater part of the book is an account of the craftsman period as remembered by the older men, and tinged by the mellow light that, fortunately for human beings, suffuses past recollections and softens their harsh features.

Space does not permit of quotations from some of the talks with old men so fully recorded. But all aspects of corn growing in the old days are attractively dealt with, even to the straw plaiting done by the women and children, and the innumerable patterns of braiding and thatching evolved in the different districts. In spite of its unpromising appearance as a plastic material, the country folk of those days succeeded in working straw into very attractive forms. There was much pride in high farming, and it seems clear that the workers extracted a good deal of satisfaction out of what appears to us to have been a trying life. The illustrations taken from Pyne's "Microcosm" (1822) suggest no hint of hard times—and yet it is certain that they were hard.

The author barely touches the modern period, and then only to condemn it. All the scientific work on the nutrition of the wheat plant, the breeding of improved varieties, and the diseases and insect pests of crops; all the engineers' efforts to make machines for the more rapid execution of the work of sowing and harvesting the crop, and the labours of the economists to find some basis for arriving at the cost of growing it—all this and much more is passed over in a few sentences. The use of nitrogenous top dressings is condemned, although a full-sized picture of a man broadcasting sulphate of ammonia is given. Clearly the author hankers after the craftsman period as seen by those looking back. But he does not explain why the craftsman period came to an end, nor does he suggest any course of action for the perplexed farmer struggling to keep his men on the land and to pay them the statutory minimum weekly wage in addition to the various extras; nor does he show how to meet the chronic shortage of farmyard manure, or to obtain seed of the old varieties of those halcyon days. No explanation is offered as to why, in spite of efforts of Governments and County Councils, the numbers of small holdings shrink, and the possibility of subsistence farming which so much appeals to the author becomes more and more remote. The plain fact seems to be that in spite of the attractiveness of the age of craftsmanship to some members of the intellectual classes, the actual workers prefer the age of science and machinery.

As one expects from the house of Batsford, the illustrations are well chosen and beautifully executed.

E. J. Russell.

PRINCIPLES OF THE REPRODUCTION OF SOUND

Elements of Acoustical Engineering
By Dr. Harry F. Olson. Pp. xv+344. (London: Chapman and Hall, Ltd., 1940.) 30*s*. net.

Dr. H. F. Olsen is in an authoritative position for dealing with the subject of acoustical engineering, and his book will be specially useful to those concerned with acoustics from the point of view of the engineer. It is well written and freely illustrated, and may be understood by anyone familiar with elementary physics and simple electric circuit theory.

The major portion of the book deals with the theory, design and testing of apparatus for the reproduction of sound. Early chapters describe fully the fundamental principles used in modern acoustics, and develop the analogies between electrical, mechanical and acoustical systems. Later chapters describe current acoustical practice in connexion with radio, gramophones, motion pictures and public address systems, and give very full accounts of the characteristics of various forms of microphone, 'pick-up' and loud-speaker.

The treatment of the various aspects of acoustical reproduction is comprehensive, and the fact that Dr. Olsen is speaking mainly about matters of which he, himself, has made a special study possibly explains why more than one quarter of the references in the book are to his own works.

On some general aspects of acoustics Dr. Olsen's treatment is naturally less comprehensive. The review of the subject of speech, music and hearing is a brief one. Supersonics is regarded as outside the scope of the work. On the instrumental measurement of noise, the book describes certain tentative American standards, suggested in 1936, in which a microphone is used in connexion with an amplifier of earlike frequency characteristics and a square law detector. No mention is made of the findings of the international conference held in Paris in 1937, which failed to accept such a standard, or to more recent developments in the objective measurement of noise. However, architectural acoustics and its measurements receive useful notice, especially in relation to the use of reproducing systems in auditoriums.

In brief, the book is to be recommended to all interested in modern acoustics, especially to those concerned with engineering aspects of the recording and reproduction of sound.

Applied Chemistry for Engineers

By Dr. Eric S. Gyngell. Pp. viii+328. (London: Edward Arnold and Co., 1940.) 15*s*. net.

THIS small volume presents in a particularly happy manner an account of many materials used by the engineer and the processes by which they are made, or in which they are used. There are no lengthy tables of analyses or detailed accounts of laboratory methods, but, instead, general descriptions and careful explanations of many terms, such as, for example, 'gas coal', 'cetane number', 'differential aeration' and 'continuous blowdown', with which the engineer is probably familiar, but might have difficulty in defining.

More than half the book is devoted to fuels and combustion, but in view of the fact that the subjects dealt with are, among others, the nature of fuels, gases and their manufacture, the distillation and synthesis of liquid fuels, methods of combustion and thermal calculations, this cannot be considered excessive.

Forty-nine pages suffice for a comprehensive account of the principles underlying corrosion and its prevention, while the remaining chapters deal briefly with paints, water treatment, cements and lubrication. So brief are these that at first sight they would appear scarcely worth inclusion, but careful scrutiny reveals the fact that the author's gift of condensation is such that very few salient points have escaped notice. A little more information about modern paints would be valuable, and perhaps a future edition will contain a chapter on plastics.

This notice would not be complete without reference to the 135 diagrams, which combine small size with remarkable clarity. Finally, although the book is written for engineers, it should be read by every student of chemistry who wishes to acquire an insight into something more than the purely theoretical side of his science. H. E. W.

A Textbook of Dietetics

By Dr. L. S. P. Davidson and Ian A. Anderson; with Diet Sheets constructed by Miss Mary E. Thomson. Pp. xviii+324. (London: Hamish Hamilton Medical Books, 1940.) 10*s*. 6*d*. net.

THE unprejudiced reader will cordially endorse the appreciation of Sir John Orr, the director of the Rowett Institute for Research in Animal Nutrition, Aberdeen, when he says in the foreword of this book that the practitioner will find in it not only precise and detailed guidance for dietetic treatment, but also a scientific and lucid account of the recently acquired knowledge on nutrition on which such treatment is based. The book, which is based on courses of lectures on the physiology of nutrition and the practice of dietetics given for several years to students in the University of Aberdeen, is divided into five parts. The first consists of a general survey of the nation's diet, past and present, with special reference to the diet at various levels of income, and the experimental, clinical and sociological data on the relation of diet to health and fitness. The second part contains a clinically complete account of the physiology of nutrition. Much of the material in this section (particularly on the vitamins) is based on very recent experimental and clinical studies. The third part is devoted to diet in health, including problems of diet in childhood, pregnancy, lactation, training and war-time. In the fourth part the dietetic treatment of established diseases is discussed. The fifth part consists of tables, recipes and diet sheets, the last of which have been constructed by Miss Mary E. Thomson, sister-dietitian to the Royal Infirmary, Aberdeen.

A bibliography of recent and almost exclusively British and American literature is appended.

The eminently practical and up-to-date character of the work renders it a most desirable addition to the library of a medical man.

Diseases of Poultry

Their Aetiology, Diagnosis, Treatment and Control; with a Section on the Normal Anatomy and Physiology of the Fowl. By Ernest Gray. (Lockwood's Agricultural and Horticultural Handbooks.) Pp. x+198+16 plates. (London: Crosby Lockwood and Son, Ltd., 1940.) 9*s*. 6*d*. net.

VERY few veterinary surgeons have thought fit to write a book on diseases of poultry. Mr. Ernest Gray has done justice to the subject and is to be congratulated on his effort. A book of this size, written by one with specialized knowledge, will add to the value of any library or private bookshelf.

Naturally a good deal of the reading matter is dry and somewhat unappetizing, but this is unavoidable in a book of this character. The section dealing with specific poultry diseases is more readable than the chapters on anatomy, physiology, pathology and feeding. The book is exceedingly well illustrated and the illustrations should prove of great value to the novice when desirous of getting to the 'root of the evil'. The author makes frequent references to writings by American workers, and also refers to some recent work by British specialists.

The book would appear to fill a place between the cheap British publications on this subject and the expensive but comprehensive works recently published in the United States. H. HOWES.

Garden Science

By Dr. John Grainger. Cheaper edition. Pp. 265. (London: University of London Press, Ltd., 1940.) 2*s*. 6*d*. net.

THE re-issue of this work at such an astonishingly low price will be welcomed by all those who are familiar with the earlier edition. It is designed to meet the needs of amateur gardeners, horticultural and agricultural students, as well as pupils of matriculation standard. Characteristics of seed and vegetative propagation, plant growth and its control by the gardener, problems of plant sterility and of pest and disease control are discussed, while considerable prominence is given to descriptions of methods used for raising improved varieties of plants, the planning of experiments and of educational gardens.

tion is to be seen to-day. This consists in a replacement of surface by overhead applications, water being supplied to plantations by powerful pumps at the rate of 3,500 gallons a minute. The actual distribution is effected by rotating overhead nozzles or projectors, possessing an effective radius of about 70 yards, that is, each projector sprays approximately three acres (Fig. 1). The tall 'risers', that is, vertical 5-in. pipes which convey the water up to the projector nozzles, are spaced throughout the plantation as required (Fig. 2). The complete equipment, comprising a power house, two large pumps, 14-in. mains, submains and laterals, thus represents a very considerable mechanical intrusion into the leafy greenery of a banana plantation. The results achieved have been very satisfactory. As to the working method, overhead irrigation is applied continuously for several hours at a time; the duration of each application is such as to provide the equivalent of several inches of rain, thus achieving the effect of a heavy, sustained, tropical precipitation. From a point of vantage the spectacle presented by the system in operation is quite remarkable, the great arcs of water, slowly swinging round, gleaming in the bright sunlight, or being resolved into miniature rainbows.

It need scarcely be said that such extensive projects have been the subject of careful costings. Notwithstanding the initial capital expenditure, the results obtained, as judged by increased production of fruit, decrease in labour costs, etc., have been such as to justify the experiment, and the system is being extended. Factors which require consideration include the fertility and probable duration of production of the area, the status of Panama disease (*Fusarium oxysporum cubense*) and its liability to rapid spread, and the proximity of adequate water supplies for pumping.

Overhead irrigation has not only proved successful as a commercial venture, but several important results, probably not anticipated, have also accrued. Not least is the fact that this method of supplying water has greatly facilitated agricultural operations on heavy clay soils, effecting, it is thought, an actual improvement in the tilth over a period of time. Further, it has made it possible to utilize for banana cultivation soils of much higher clay content than had hitherto been deemed possible or advisable. This is a very important consideration, since clay soils have not only proved productive of good fruit, but are also 'resistant' to the inroads of Panama disease. To what extent the conquest of clay will eventually be extended by overhead irrigation, in conjunction with other innovations, is a question that cannot fail to command the attention of all interested in tropical agriculture. It will suffice to say that a high standard of production is to-day being obtained on clay soils which twenty years ago would have been omitted from any well-considered planting programme.

A characteristic of the cultivation of the Gros Michel on heavy clay soils is that the initial growth tends to be somewhat tardy, so much so that planters may be induced to think that their venture has been ill-advised and destined to failure. Experience has shown, however, that if fertilizers are applied during the first few months, the initial lag is greatly reduced; plants improve progressively with age, especially after the foliage canopy is established, and consistently good yields may be obtained. Such detailed attention to potentially productive areas is now part of the working policy of the larger companies and is in sharp contrast to the method of exploitation followed by abandonment of former days. The aim, in brief, is the highly commendable one that all sections of a farm shall be so worked in respect of fertilizing, pruning, spacing, etc., as to make for a good general standard of productiveness.

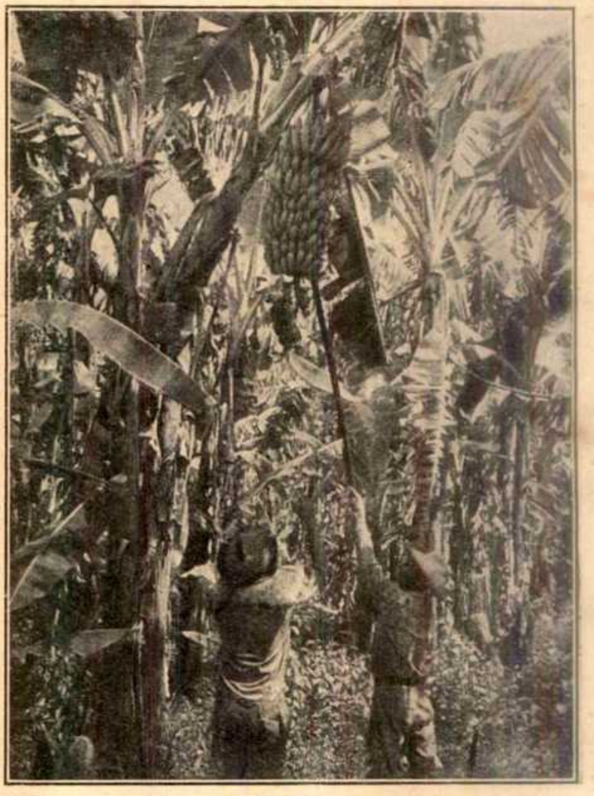

Fig. 3.

HARVESTING OF FRUIT, HONDURAS.

Reference has been made to the losses periodically caused by floods. These inundations are violent but usually of brief duration. They may prove exceedingly destructive, taking a heavy toll not only of plants and fruit, and leaving plantations a wilderness of smashed vegetation smeared with several inches of mud, but also permanent railroads and bridges may be swept away. The path of the flood water is determined by topography, fertile areas in the river bends being especially subject to inundation and erosion. A recent experiment of very considerable interest and practical value lies in the utilization of the silt-laden flood water, which is contained and controlled by channels and levees in such a way that its burthen of earthy matter is deposited in selected low-lying areas. Each flood—and several may occur in one year—thus results in the deposition, in swampy areas, of several inches of friable and fertile top soil, eroded from higher up the valley. In a surprisingly short space of time—a few years at most—hitherto valueless low-lying areas are so built up that they can be drained and planted with bananas. This useful work is now being undertaken on a not inconsiderable scale.

In the banana lands of the Ullua River (Republic of Honduras) such reclaimed areas can be seen to-day. They are supporting excellent stands of young plants, and the incidence of Panama disease was, as observed by me at the beginning of 1940, negligible. Such innovations are of the greatest significance in the agricultural development of Central America. They mark the transition from the impermanence and rough-and-ready exploitation of other days to the rational utilization of natural resources and to that permanence which should result from a system which aims at the maintenance of a high standard of productivity in favourable localities. To the consumer on distant markets, such preparations for the future also bring the assurance that there will be no abatement in the supplies or quality of the product to which he has become accustomed.

Some fifteen to twenty years ago, with the abandonment of vast areas on account of Panama disease and deterioration of fertility under continuous single crop cultivation, the question was frequently mooted as to the fate of the banana industry when all the good virgin areas became used up. The question is still asked and it may now be answered. So far as Central America is concerned, there seems no reason for supposing that production will seriously decline for many years to come. In recent years, there has not only been adequate production on the major properties, but actually over-production of bunches of the first quality. Extensive areas, mapped for banana growing, have not yet been touched, other new and highly productive areas are being developed on a very conservative scale, and, as indicated above, existing plantations are not only being maintained in first-class condition but also are being daily added to by the control of flood water.

To the agriculturist as to the layman, the spectacle of a modern banana division, comprising some sixty square miles under cultivation, with surface and overhead irrigation provided where necessary, and supplied throughout with a pipeline system for the application of Bordeaux Mixture (used to control Cercospora leaf disease), is one that engenders confidence for the future. To those who have been responsible for such notable achievements, and for much courageous experimentation on a grand scale, great credit is due.

THE BIRTH OF GLACIAL GEOLOGY*

BY DR. WILLIAM J. McCALLIEN
CARNEGIE TEACHING FELLOW, UNIVERSITY OF GLASGOW

THE year 1840 will always be remembered as one of outstanding importance in the annals of geology. So far as Great Britain is concerned, glacial geology was born in 1840 with the visit to this country of Louis Agassiz. Glasgow will always be associated with this event, for Agassiz attended the tenth meeting of the British Association which was held there in the summer of 1840. At the meeting he took the opportunity of proposing the revolutionary theory "that at a certain epoch all the north of Europe, and also the north of Asia and America, were covered with a mass of ice". Woodward, in his "History of Geology" (1911, p. 121) has said: "Since the days of William Smith no more momentous, and, as time has proved, no sounder, explanation of a vast and difficult problem had been given in geological science."

Agassiz wrote: "In the early part of the summer of 1840, I started from Switzerland for England with the express object of finding traces of glaciers in Britain. This glacier-hunt was at that time a somewhat perilous undertaking for the reputation of a young naturalist like myself, since some of the greatest names in science were arrayed against the novel glacial theory. . . ."[1]

---

* Part of an address to the Geological Society of Glasgow on December 14.

Towards the end of this essay Agassiz continues : "Of course the ancient glaciers of Great Britain were far more difficult to trace than those of Switzerland, where the present glaciers are guides to the old ones. Nevertheless, my expectations were more than answered. The first valley I entered in the glacial regions of Scotland was barred by a terminal moraine . . . the surface of the country [was] polished, grooved, and scratched, as in the region of existing glaciers, presenting an appearance corresponding exactly to that described elsewhere . . .". The satisfaction which Agassiz experienced on this occasion was probably equalled only on the excursion which he made from the steamer on first setting foot on the American continent in 1846.

Before considering the events of 1840 further, let me give a very brief account of the state of knowledge regarding superficial deposits and surface phenomena in general before that time. It is not my purpose to enter into details concerning the history of glacial research. Such a summary will help us to appreciate the far-sighted nature of Agassiz' conclusions.

As Agassiz himself said, it was at that time much easier to believe in the former extension of ice in the Alps than in the glaciation of the British Isles. We turn to the Alps, therefore, for information about glaciers, and we find that so far back as 1787 Kuhn believed in the former extension of the Grindelwald Glacier. Later, de Saussure, Hugi, Venetz, and Charpentier all emphasized the significance of valley moraines standing outside the limits of existing glaciers. In 1829, Venetz suggested the extension of the ice far beyond the mountain valleys to the great erratic blocks which lie on the slopes of the Jura Mountains. The existence of these enormous granite blocks had been pointed out by de Saussure, but the first actual suggestion that they were ice-carried came from James Hutton. Hutton never saw the boulders himself; he knew of them only through the writings of de Saussure. Before this it was generally believed that they had been transported by a great deluge, but according to Hutton's philosophy "general deluges form no part of the theory of the earth". Hutton's suggestion, however, was forgotten.

Hutton's famous disciples, James Hall and John Playfair, were more fortunate than their master, for they studied the granite blocks in the field. Hall followed de Saussure in attributing their transport to a gigantic wave. Playfair, confronted in particular with a block weighing some 2,520 tons at a distance of seventy miles from its source and with its corners conspicuously unrounded, came to the conclusion that "A glacier is the only agent we now see capable of transporting them to such a distance, without destroying that sharpness of the angles so distinctive of these masses"[2].

Venetz rediscovered the solution to the problem of the erratics and he was followed by Charpentier in 1834. Venetz and Charpentier may be considered the real founders of glacial research. Agassiz went further than both in his observations and from these he made deductions undreamed of by his masters.

It was under the personal guidance of Charpentier that Agassiz began his investigations of the Rhone erratics in the summer of 1836. This study, coupled with his knowledge of the literature, in a very short time led him to his great theory. In the winter of 1836–37 he lectured at Neuchâtel on the Ice Age and propounded the theory that the ice originally extended over the Alps as far as erratics, polishing, and striæ occur. Agassiz soon realized that the former extension of the Swiss glaciers must have resulted from some general lowering of temperature. In 1840 he published an account of glaciers in general, and in this he propounded the glacial theory. At that time he knew northern Europe only from the writings of others, and he was familiar with the striæ, moulding, and erratics of the Edinburgh district through the published descriptions of James Hall. It only remained for him to test his theory in the British Isles.

There is no doubt that up to the time of Agassiz' visit the superficial phenomena of Great Britain were looked upon as the work of a great deluge usually identified with the Biblical flood. The nearest approach to glaciers was the suggestion of iceberg-carry proposed by some writers.

Dr. Buckland of Oxford, one of the most influential writers of the 'golden age of geology', was the great champion of the geological proofs of the Biblical flood. At his inaugural lecture at the University of Oxford in 1819, Buckland announced that a universal flood is proved so decisively "that had we never heard of such an event from Scripture or any other authority, Geology of itself must have called in the assistance of some such catastrophe to explain the phenomena of diluvial action".

By 1837, however, Buckland was wavering in his support of the flood to the extent that he wrote that "This important point, however, cannot be considered as completely settled till more detailed investigations . . . shall have taken place." By this time Venetz, Charpentier, and Agassiz had made great strides with the interpretation of the surface features and deposits of the Alps. Glacial action in the ice-free valleys and mountain slopes were recognized by signs which Buckland realized were identical with the very phenomena he knew so well at home, and which he explained by a great deluge. He went to Switzerland in 1838 to visit Agassiz and see the evidence for himself. Of this visit Sollas has written, "a few days' personal investigation sufficed to convince Buckland of the truth of Agassiz' opinions". At the same time he must have been quite convinced in his own mind of the former glaciation of Britain, for he persuaded Agassiz to visit this country in 1840.

Let Agassiz tell the story in his own words: "Only one of my older scientific friends in England, a man who in earlier years had weathered a similar storm himself, shared my confidence in the investigations looked upon by others as so visionary, and offered to accompany me in my excursion to the North of England, Scotland, and Wales. I cannot recur to that delightful journey without a few words of grateful and affectionate tribute to the friend who sustained me by his sympathy and guided me by his knowledge and experience.

"For many years I had enjoyed the privilege of personal acquaintance with Dr. Buckland, and in 1834 when engaged in the investigation of fossil fishes, I had travelled with him through parts of England and Scotland, and had derived invaluable assistance from his friendly advice and direction. . . . A few years later he visited Switzerland, when I had the pleasure of showing him, in my turn, the glacial phenomena of my native country, to the study of which I was then devoting all my spare time. After a thorough survey of the facts I had collected, he became satisfied that my interpretation of them was likely to prove correct, and even then he recalled phenomena of his own country, which, under the new light thrown upon them by the glacial phenomena of Switzerland, gave a promise of success to my extraordinary venture. We then resolved to pursue the inquiry together on the occasion of my next visit to England; and after the meeting in Glasgow of the British Association for the Advancement of Science, we started for the mountains of Scotland in search of traces of the glaciers, which, if there was any truth in the generalizations to which my study of the Swiss glaciers had led me, must have come down from the Grampian range, and reached the level of the sea, as they do now in Greenland"[3].

The results of the Scottish tour were communicated to the Geological Society of London in November, 1840[4]. Sir Archibald Geikie has said that the views expressed by Agassiz and Buckland "were violently opposed and sarcastically ridiculed at the Society's Meetings when they were communicated"[5].

There is only an abstract of Agassiz' Glasgow address in the Report of the British Association. It seems to have covered much the same ground as was described in detail in the same year in "Études sur les Glaciers". At the Glasgow meeting he propounded the theory "that at a certain epoch all the north of Europe, and also the north of Asia and America were covered with a mass of ice. . . . "From his studies of the Alpine glaciers Agassiz was led to recognize the former existence of ice in Britain. Hutton's own doctrine that the present is the key to the past partly explains why he and Hall failed to recognize glacial phenomena in Scotland and why it was left to one familiar with modern glaciers to make the discovery.

We cannot close this account of 1840 without mention of James Smith of Jordanhill, who was president of the Glasgow Geological Society during 1851–67. Smith read a paper at the Glasgow meeting of the British Association in 1840 in which he pointed out the presence of shell-beds forty feet above sea-level and containing shells of arctic species now extinct around our shores. James Smith was the first observer to bring forward convincing evidence of the lowering of general temperature of our latitudes. He was the pioneer of glacial palæontology. Another of Smith's claims to fame is the share he had in launching A. C. Ramsay upon a scientific career. Ramsay exhibited his model, map, and sections of Arran at the Glasgow meeting of 1840, and it was as a result of this work that he joined the Geological Survey, of which later he became director general.

Bailey has aptly said that the glacial theory, launched in 1840, "registered an attack rather than a victory" and that for years to come it "seemed to have been repulsed". It was not until 1863 that land ice finally displaced icebergs and succeeded in claiming the greatest share in the glaciation of our country. In that year Sir Archibald Geikie published his famous paper "The Glacial Drift of Scotland"[6].

Although Geikie's paper of 1863 brought an end to the period of stagnation in glacial research that followed the announcement of the glacial theory, two important papers were published in the previous year: Ramsay's account of the glacial origin of rock-basins[7] and Jamieson's conversion from floating ice to land ice as a result of his tracing of ice-moulding uphill from Loch Fyne westward towards the Atlantic[8].

OBITUARIES

Dr. Cresswell Shearer, F.R.S.

Dr. Cresswell Shearer, who died at Cambridge on February 7, after a brief illness, will be remembered as one of the most interesting personalities in the ranks of British zoologists.

As a young man Shearer took a medical degree at McGill University, but his main scientific interests lay in the field of experimental embryology. He spent much time at Naples at a period when the Stazione Zoologica was perhaps at the zenith of its fame. There he met many of the great figures of late nineteenth century biology, and his recollections of this period were afterwards a constant source of delight and instruction to his own Cambridge pupils. In 1910 he settled in Cambridge, and shortly afterwards was appointed the first of a series of University lecturers in experimental zoology. The next decade was a period of active and productive research. They were also, however, years of unusual inspiration to students. His lectures were almost invariably unorthodox in presentation, if not in substance, but they gave a real insight into contemporary biological thought and threw into relief the lines along which future progress seemed likely to come.

Prior to the War of 1914–18, Shearer had published a number of important papers on the development of trochosphere larvæ and on sex determination in Dinophilus. In 1913 the *Philosophical Transactions of the Royal Society* contained the well-known monograph on "The Experimental Hybridisation of Echinoids", which was the result of Shearer's work in collaboration with W. de Morgan and H. Munro Fox. This work was carried out at Plymouth, where many of his pupils followed him in the summer months of each year. During the War, he returned to medicine and worked in the west of England. Here began many years of happy married life.

Shearer was elected a fellow of the Royal Society in 1916, and in 1918 returned to Cambridge to carry out a series of important researches on the effect of fertilization on the metabolism of the eggs of sea urchins. He showed, for the first time, that spectacular changes in oxygen consumption occur for a few seconds after the spermatozoon has entered the egg.

Shearer's versatility was perhaps one of the most characteristic features of his University career. He worked first in the Department of Zoology, then in those of Pathology, Physiology, and finally Anatomy, keeping in close contact with the younger research workers in all these and other laboratories. For several years he held the post of University lecturer in embryology in the Department of Anatomy. On his retirement from University work, he returned once more to the Zoological Department, much to the pleasure and advantage of the Department.

Apart from his biological interests, Shearer was a man of wide general learning. His knowledge of medieval Italian architecture was profound, and in 1935 he published "The Renaissance of Architecture in Southern Italy". It is to be hoped that his later work will also be made available to those interested in this field of learning. His ability as an artist and his enthusiasm for photography were not only of great value to him in both his scientific and literary work, but also gave very considerable pleasure to his friends.

Shearer was a man of rather retiring disposition, but once the thin crust of his reserve was broken, he revealed a warm-hearted and most generous nature. His memory will not readily fade. J. Gray.

Dr. J. G. Priestley

By the death of John Gillies Priestley, which occurred on February 9 at the age of sixty-one, the School of Physiology at Oxford has suffered a loss which it can ill afford, especially at this critical time when university education is faced by endless difficulties arising from the War. He was, it is true, somewhat reticent by nature, but those who knew him best gained in his friendship something that they prized. A man of great personal charm, generous to those in need, he was always ready to interrupt his own work to give help and advice to any who sought it. With a balanced judgment on the work of others, he was hypercritical of himself and modestly diffident of his own powers. Meticulously accurate in his experimental methods, no trouble was too great for him to take in his research work, and in his teaching he always tried to inculcate into his pupils some of his own gift for accurate observation and attention to detail. With a quiet courage and determination that was characteristic he fought against ill-health that told more and more upon him as the years passed, publishing his final paper in December 1940, and resigning his readership only a few weeks before his death when he knew that he had no longer strength to fulfil the duties of his office.

Priestley was educated at Eton and gained an open scholarship at Christ Church in 1898. It was whilst reading physiology at Oxford that he became acquainted with John Haldane, whose friendship was to have a great influence on his future career. As soon as he had taken his degree in 1902, he joined Haldane in an investigation which resulted, in 1905, in the publication under their joint authorship of that remarkable paper on the "Regulation of the Lung Ventilation" which was to play so large a part in the development of physiological knowledge. Leaving Oxford he then went to St. Bartholomew's Hospital to complete his clinical studies. After gaining his medical qualification he became house physician to Sir Wilmot Herringham, whose high opinion he won. After working for a year with Falta in Vienna he returned to St. Bartholomew's to take charge of the new Laboratory of Chemical Pathology which had just been opened, but within two years he developed tuberculosis of the lungs and had to go to Davos for treatment. The disease was checked, but pulmonary fibrosis left him with a legacy of ill-health, which was all the more tragic to a man who had a great interest in out-door sport and big game shooting, and had been a distinguished oarsman at Oxford.

Returning to Oxford in 1913 he began a series of investigations into the part played by the kidneys in the regulation of the composition of the blood, but this work was soon interrupted by the outbreak of the War of 1914–18. He volunteered at once, and was given a commission in the R.A.M.C. on September 1, 1914. Serving in France and Belgium he was in the following year awarded the Military Cross and was mentioned in despatches. He was wounded at Neuve Chapelle. Later in the War he was associated with Haldane and Meakins in an investigation into the after-effects of war-gas poisoning. When peace came he was appointed reader in clinical physiology at Oxford. His further investigations included work on various aspects of the physiology of respiration, on the function of the kidney, on some problems of general metabolism, and, more recently, he was engaged on a critical examination of methods for ascertaining the output of the human heart. He was again, and most appropriately, associated with Haldane as joint author of a new edition (1935) of Haldane's book "Respiration". With a clear appreciation of the relationship of physiology to medicine he was largely responsible for initiating a practical course of human physiology in the Final Honour School of Physiology, which led to the publication of "Human Physiology; a Practical Course", now in its second edition, of which he was joint author. For the Physiological Society he prepared a subject index of the first sixty volumes of the *Journal of Physiology*, and he succeeded John Mellanby in the editorship for a few years of *Physiological Abstracts*, a task in which his expert knowledge of the international decimal system for the classification of scientific papers proved of great service.

He leaves a widow, and a son, Major Charles Priestley.

C. G. Douglas.

Dr. Alexander Bowman

Among the men of science who have guided fishery research in Scotland, and they form a distinguished company, Dr. Bowman was marked by a grasp of the practical problems of the fisheries and of the scientific efforts which must lie behind the solution of these problems.

Yet scientific work was not his earliest notion of a career. He began by helping his father in a prosperous business in Aberdeen, and then proceeded to take the normal training for a teacher at the Free Church Training College in that city. It was after these first essays that he decided to enter the University, and to study for a degree in science. He graduated in the University of Aberdeen with distinction in zoology, and was awarded the Fullerton research scholarship in natural science, but before the completion of its tenure he resigned on being appointed naturalist to the Fishery Board for Scotland.

There he worked in collaboration with Sir D'Arcy Thompson, scientific member of the Fishery Board, and his early activities were centred upon the research steamer *Goldseeker* and the amassing of enormous collections made during the periodic voyages of that vessel, which were to help in explaining the movements of waters, the changes of salinity, the distribution of food materials, and thus to interpret the movements of the fishes themselves. Later he applied himself with great success to the solution of practical fishery problems, such as the elucidation of the enormous fluctuations in fish supplies, the forecasting of future yield, the effect of the size of mesh in influencing escapes of undersized fish, and so on. During these years he worked almost single-handed and with great devotion, spending month after month at sea in the stormy northern waters, laying the foundation of his vast knowledge of the fisheries in their scientific and practical aspects. In 1908, Dr. Bowman obtained the degree of D.Sc. at the University of Aberdeen for a thesis containing some of his pioneer work in the experimental study of fishing methods, notably on the otter trawl and its effect on the stocks of fish. His experience of fishery research was widened by periods of study in Denmark and Germany.

On the sudden death of Mr. Nelson, who had just succeeded Dr. T. Weymss Fulton as scientific superintendent of the Fishery Board for Scotland, Dr. Bowman was appointed to fill the post in 1923. In this position he developed his earlier researches and enlarged the scientific staff of the Board. An excellent example of the value of his methods is to be seen in his work upon the haddock, which has formed the foundation of the most thorough-going knowledge of one of our most important food fishes. He considered that one of his greatest honours was his appointment in 1925 as chairman of the Northern North Sea Committee of the International Council for the Exploration of the Sea, but the choice was not surprising, for his colleagues at home and abroad had the greatest respect for his knowledge and judgment, and he was properly regarded as one of the best fishery experts of his time.

Dr. Bowman's training as a teacher was made use of by the University of Aberdeen when it appointed him lecturer in the scientific study of fisheries, and in Aberdeen and the surrounding district he conducted classes in marine zoology for teachers and delivered popular lectures on natural history. In 1933 ill-health compelled him to resign from his post, and a lingering illness ended his life on January 14, when he was in his sixty-fifth year.

We regret to announce the following deaths:

Prof. F. A. P. Aveling, University professor of psychology in King's College, London, on March 6, aged sixty-five.

Miss Ethelind Gardiner, for thirty-five years secretary of the Royal Society for the Protection of Birds, on March 1.

Sir George Grierson, O.M., K.C.I.E., the Oriental scholar and compiler of the "Linguistic Survey of India", on March 7, aged ninety.

NEWS AND VIEWS

Nature and the War

Under the title "An American Message", we publish on p. 329 of this issue a complimentary note from the managing editor, associate editor and staff of the *Bell Laboratories Record*, the monthly journal of the Bell Telephone Laboratories, Inc. These Laboratories, which form one of the largest industrial research centres in the world, are well known to physicists and engineers for their research on electronic physics, chemistry, magnetism, optics, radio, applied mathematics, speech and hearing, and generation and modulation of electrical currents. Such a communication is very encouraging, and no doubt British readers will receive it with pleasure. This American message is merely a reflexion of the main body of opinion in the United States, finally endorsed by the signing of the Lease and Lend Bill by President Roosevelt on March 11, after it had been approved by the House of Representatives by the overwhelming majority of 317 to 71.

The letter is one of a large number already received, though this is the first from a group of men of science —the others having been sent by individuals. Nature is still carrying on despite the many and varying difficulties caused by the War and the air attacks on London. The subject material has, perforce, been modified, especially in the case of the physical sciences, since certain material must obviously be withheld for defence reasons. Furthermore, little material can be expected from countries outside the British Commonwealth and the Americas. This has caused a reduction in the correspondence columns, and the international character of Nature is thus temporarily impaired. This is regrettable, though it is difficult to conceive of any other situation, since even if communications abroad were still open between Great Britain and those countries at present closed to postal communication the editors of Nature would still pursue vigorously their policy of gathering the forces of science to help in the fight against aggression and against those at present repudiating and even suppressing truth and encouraging the propagation of falsehood.

Though situated in an area which has certainly had a share in the wanton destruction resulting from indiscriminate bombing, we are glad to say that, so far, the offices of Nature have suffered nothing but a few broken windows and occasional interruption of of work caused by the proximity of delayed-action bombs. In any event, arrangements have been in existence for some considerable time for Nature to carry on elsewhere in the unhappy event of its present home becoming uninhabitable for any length of time.

War and Scientific Research

In an article in the *Quarterly Review* of January on the effect of the War on scientific research, Mr. J. M. Watson emphasizes the extent to which fundamental, long-range research is interrupted by the necessity of concentrating effort on the solution of urgent day-to-day problems and investigations related directly to the war effort. The whole course of hostilities is profoundly affected by pure research, pursued in peace-time for no ulterior motive; meteorology and wireless telegraphy provide outstanding examples. But in spite of the great volume of special research instituted for the prosecution of the War, the general effect upon scientific advance is one of stultification. Moreover, it is the application of known principles rather than the discovery of new ones which provides the solution of urgent problems, and the reduction or cessation of pure research in war-time not only retards the progress of science but also interrupts its stimulating and fertilizing effect on all scientific work, including *ad hoc* research. Mr. Watson also refers to the lack of co-ordination between scientific advisers and executive authorities which hampers progress, as well as to the danger which attends the absence of a scientific outlook in circles wielding political and executive power. Moreover, the scientific outlook and the results of scientific research must play an even bigger part in post-war reconstruction than in the War itself.

The problems which confront the research worker in war-time are placed by Mr. Watson in six main groups. The first of these includes the medical and surgical problems, whether of epidemic disease, the treatment of wounds, the treatment or prevention of secondary infections of wounds, or the investigation of means of promoting speedier healing. The second group embraces problems relating to the supply of raw materials, on which so much German effort has been concentrated. The War has given a tremendous stimulus to industrial research in the use of synthetic plastics. The third group includes problems relating to the production or improvement of weapons of war, including the various precision instruments and such problems as those of camouflage, where Mr. Watson stresses the importance of the psychological factor. In the fourth group of problems, relating mainly to the civilian population, which have been comparatively neglected until very recently, the difficulties are concerned with social research and education and with effective control of vested interests, rather than with scientific research. This group includes such matters as agricultural research, nutrition, the nervous disorders arising from aerial bombardment and like aspects of public health. Problems summarized under the heading of public relations, notably propaganda and morale, and the scientific investigation of matters bearing on industrial efficiency, such as hours of work, ventilation, lighting, noise, etc., comprise the fifth group, while in the sixth group are to be placed the entirely new set of investigations arising from the introduction of air raid precautions.

The National Day of Prayer

HIS MAJESTY THE KING, having expressed a desire that March 23 should be observed as a national day of prayer, statements have been issued by leaders of religious bodies in Great Britain. Dr. Lang, the Archbishop of Canterbury, after observing that "we are now approaching or entering a critical stage in the tremendous struggle", considers it most fitting that the King, as head of the nation, "should once again call it to renew the acknowledgement of its need of God and dependence on Him", and to pray for "His forgiveness of all that has been amiss in our national life, for strength and guidance in the stern and testing days which may be coming, and, if it be His will, for good success". The Primate observes also that with such prayers it is right that "we should offer thanksgivings for mercies already received", alluding to "the wonderful way in which we have escaped the dangers which surrounded us last summer and autumn". His Eminence Cardinal Hinsley, Archbishop of Westminster, declares that, "the stern trials that face us call for the light and strength which God alone can give. Moreover, the mercies we have received in answer to prayer should cause us to lift up our hearts in thanksgiving to 'the God of all consolation' ". His Eminence also urges the faithful "to pray that this deadly strife among nations may speedily end in a true peace based on justice and love".

The statement issued by the Rev. Sidney M. Berry and the Rev. S. W. Hughes, on behalf of the Free Church Federal Council, appeals to Free Churchmen throughout the country to observe the Day of Prayer. "The struggle in which we are now engaged they declare, "will never issue in the kind of world we want to see by relying merely on the power of material weapons and resources. Our supreme need is for God's guidance and strength". They urge that the day of prayer be freed "from any false ideas that prayer is a kind of magic, or that we only turn to God when we are at our wit's end". To be truly observed the day must mean "a dedication of ourselves through days of peril into those other and happier days of victory and peace, when dangers of another kind may come to us". The Chief Rabbi, Dr. J. H. Hertz, in his statement declares that "his Majesty's Jewish subjects will loyally obey the royal summons", using "supplications to our Father in Heaven for strength and guidance, as well as prayers of thanksgiving for the mercies and victories hitherto granted to the forces of freedom".

Railways under War Conditions

THE vigorous defence of the operation of the railways under war conditions, which Lord Stamp offered in his chairman's address at the annual general meeting on March 7 of the London, Midland and Scottish Railway Company, contained an interesting reference to the work of the Company's Research Department, the very great value of which in solving war-time problems he emphasized. Such problems as substitute materials, salvage, air raid precautions and black-out could only be solved quickly and effectively by scientific methods. Lord Stamp referred particularly to the work of the Research Department on treatment of the windows of signal boxes without interfering with clear vision, which had proved so effective that in the boxes so treated not a single man had been injured by glass splinters ; the importance of this in maintaining confidence and operating efficiency can be imagined. With the lighting section, the Research Department has also contributed to the development of scientific methods, enabling a combination of safety from observation with the best permissible lighting to be used in dealing with the innumerable problems of lighting the black-out in goods sheds, marshalling yards and elsewhere. Lord Stamp's spirited reply to criticism, which has sometimes been somewhat irresponsible and carping, made it clear that the handicaps on the railways and the strain on their reserves could be mitigated by intelligent forethought on the part of the Service Departments. It may be hoped that his indictment of want of foresight or worse will not escape the notice of that invaluable watch-dog over administrative weaknesses—the Select Committee on National Expenditure.

British Medical Students in the United States

THE Minister of Health, replying in the House of Commons to a question by Prof. A. V. Hill, said that he was aware that an offer had been received from the Rockefeller Foundation in New York to undertake and provide for the clinical training and maintenance of selected British medical students in medical schools in the United States of America and in Canada. A committee to select students has been set up in Great Britain under the chairmanship of the Vice-Chancellor of the University of Manchester, Prof. J. S. B. Stopford, and consisting of Prof. H. R. Dean (vice-chairman), Prof. H. W. B. Cairns, Mr. H. L. Eason, Prof. G. E. Gask, Mr. G. F. Gibberd, Dr. A. M. H. Gray, Prof. A. V. Hill, Surgeon Rear Admiral J. W. McNee, Sir Walter Moberly, Sir Franklin Sibly and Mr. W. B. Brander, of the Universities Bureau of the British Empire, c/o University College, Gower Street, London, W.C.1 (secretary). The first group of students will leave for America as soon as possible.

The Rockefeller Foundation's grant is of 100,000 dollars, and will suffice for about twenty-five studentships, providing cost of tuition and maintenance for two or three years. It comes at an opportune moment, when clinical studies in Great Britain are of necessity being continued under difficulties imposed by shortage of teaching staff, many of whom are on active service, and by damage caused to some of the leading hospitals by enemy action. The selected students will go to various universities in the United States and Canada, where they will be able not only to complete their medical studies, but also to obtain valuable experience of practice and research in North America. This generous grant is yet one more demonstration of the desire to help and practical interest of the United States in the preservation of European standards of life.

Economy in Drugs

A MEMORANDUM on "Economy in the Use of Drugs in War Time" by the Therapeutic Requirements Committee of the Medical Research Council has been issued as an official publication. It is based on the provisional lists circulated last autumn, a summary of which appeared in NATURE (October 12, 1940). These lists have been thoroughly revised and greatly extended. Some five hundred drugs are classified into three groups: (1) essential or readily available; (2) essential for certain purposes but in the use of which strict economy should be observed; and (3) not essential. By a recent Defence Regulation, the Ministry of Health was empowered to make Orders authorizing the replacement of scarce drugs by alternatives having substantially the same therapeutic action; it is understood that the Medical Research Council is the body which advises on essential and non-essential medicinal substances, and consequently this memorandum is of no little importance, since it may be taken that it gives at least some indication of the drugs which may be the subject of Orders. In the meantime, medical men are expected to avoid the prescription of drugs in classes 2 and 3 so far as possible. Of more permanent interest is an appendix to the memorandum, consisting of the names of drugs which, in the view of the Medical Research Council, should be produced in the British Empire and should be encouraged.

Post-War Building and Planning

SOME aspects of the problem of post-War building are discussed in *Electrical Industries* of February. It seems clear that some limitation of the size of our future towns and cities will have to be seriously contemplated. This, in turn, will inevitably give rise to many indirect problems of a complicated nature. From the point of view of electrical supply, no matter what type of building in our reconstructed areas is finally decided on, the vast potentialities for the extended use of electricity can readily be visualized; especially when we bear in mind that the work of reconstruction will not only be confined to housing, but will also embrace industry and its location. The general plan of reconstruction will probably take into consideration, besides the bombed areas, those slum clearance schemes held in abeyance for the duration of the War. It would be dangerous to encourage the public to expect too much from post-War reconstruction, especially in its early stages, and already a warning has been issued by Lord Reith on this subject. So far as electric supply authorities are concerned, many of the pre-War development schemes which have necessitated, or will necessitate, the laying down of new sub-stations and networks to cater for future requirements may have to be drastically revised. One of the most important points is that when normal times return and the preliminary surveys are made, the electric supply industries, assisted by such bodies as the Electrical Development Association, the British Standards Institution and the British Electrical and Allied Industries Research Association, should be in a position to place immediately before the appropriate authority the electrical position in its entirety.

Air Raid Damage to the London Museum

THE damage sustained by the London Museum has been confined almost entirely to its glass. The major portion of the windows on the south front, the glass in the lantern of the Main Hall and that of the lantern in the Costume Gallery, which was of ground-glass, decorated with allegorical figures, have been destroyed. The matchless gilded ceilings and the painted panels have, however, escaped damage, and even the original chandeliers and candelabra have been in the main uninjured. Before the outbreak of war, most of the collections were removed from the building, only some of the more cumbrous exhibits and models being left in the basement, and a small collection of less important duplicate material being retained for special exhibitions, and for the illustrations of a course of lectures, which was given in the early part of last year. The collections are thus intact, even the material remaining in the building being unharmed.

Alcohol and Vitamin A

IN a recent issue of *Science* it is claimed by Drs. Samuel W. Clausen, Burtis B. Breeze, William S. Baum, Augusta B. McCoord and John O. Rydeen, of the University of Rochester School of Medicine and Dentistry, that taking alcohol raises the vitamin A content of the blood in men as well as dogs. 'Before-and-after' tests were made on ten persons taking alcohol in the form of mixed drinks as desired. In every case the amount of vitamin A in the blood was increased after the drinking. The increase was relatively slight in most cases but was remarkably large in one person who had a high level of vitamin A in his blood before the drinking. Night-blindness is one of the chief signs of lack of this vitamin, although it is required for health of other parts of the body besides the eyes, and for normal growth of children.

Tests of ability to see in the dark, one method of determining whether a person is getting enough vitamin A, made after drinking, showed unaccountably short recovery time in dark adaptation. Dr. L. B. Pett, of the University of Alberta, who made this observation, suggested that the reason was the mobilization of vitamin A from its storage place in the body, presumably the liver, to the blood, which would distribute it to other parts of the body including the eyes. The vitamin A tests reported by the Rochester scientific workers were made on the blood, not the eyes. They also believe that the increase in blood vitamin A after alcohol is due to a mobilization of the vitamin from other tissues. They suggest that this might form the basis of a test for vitamin A storage in the body.

Alcohol and Brain Metabolism

IN a recent paper (*Amer. J. Psychiat.*, 97, 385; 1940), Drs. Walter W. Goldfarb, Karl M. Bowman and Joseph Wortis of the Psychiatric Division, Bellevue Hospital, New York, report the effects of ethyl alcohol on the metabolism of the brain in ten patients admitted to hospital presenting the clinical picture of acute alcoholic intoxication. The estimation of cerebral metabolism was based on the difference between the concentrations of various substances in the arterial and venous blood of the brain. The arterial blood was taken from either the brachial or femoral arteries, and the venous blood from the internal jugular vein. During the condition of acute intoxication the cerebral uptake of oxygen was diminished in six cases and within normal limits in four, while after recovery the uptake of oxygen was within normal limits in all cases.

Whale Marking

AFTER a considerable amount of experimenting the Discovery expedition evolved a satisfactory device for marking whales, in the form of a stainless steel tube 10 in. long that can be fired from a 12-bore gun. In the four seasons 1934–38 a total of 5,219 whales of six species was considered to be satisfactorily marked. G. W. Raynor (Discovery Reports, 19; 1940) describes the methods of marking, the data provided by the marks so far returned and discusses their significance. Of the three main species to be marked, the Blue, the Fin and the Humpback, there have been 187 returns out of 1,513 marked. This is not a large number, and it will obviously be increased in the course of time; but in view of the present conditions it was considered advisable to publish the results so far obtained. The Blue stock is being depleted faster than the Fin stock; but the Humpbacks are suffering most heavily. Blue whales round South Georgia are not a stationary group but move west towards the end of the whaling season. Similarly, Fin whales, although they may remain longer, move off to the south. The Humpbacks probably have an annual migration from the Antarctic to the north-west coast of Australia and to Madagascar. They also tend to remain more together and so do not exhibit the dispersal shown by the other two stocks. The dispersal is not quite so marked in the Fins, so that there appear to be "provinces" within which there is considerable movement but between which there is very little exchange of stocks.

The Heating of Buildings

AT a meeting of the Newcomen Society, held at the Institution of Civil Engineers on February 12, Mr. A. F. Dufton read a paper entitled "Early Application of Engineering to the Warming of Buildings" in which he reviewed the improvements of fire-places and stoves, and the introduction of heating by steam and hot water. The old open fire-place has long been recognized as a most wasteful and inefficient means of heating a room, and it was to economize fuel that Franklin in 1745 introduced the Pennsylvanian fire-place by which he reckoned to save five-sixths of the fuel. Many years before Franklin, a French physician, Nicholas Gauger, had published a work, "La Mécanique du Feu", and had described the ventilating fire-place. In his work he referred to a form of such fire-place which had been installed in the library of the Louvre. Steam heating was used by Watt as early as 1784, but his tin-plate radiation was not satisfactory. Sir John Leslie's experiments in radiant heat had not then been made. Among the pioneers of heating Rumford was one of the most successful, and in his writings pointed out the necessity for double-windows to rooms. Strutt of Derby was another pioneer of this time. Heating by hot water was used in France in 1777 by M. Bonnemain for his chicken incubators, and to Perkins we owe the use of the high-pressure hot-water system. Another improver of stoves was Dr. Neil Arnott, who in 1854 was awarded the Rumford Medal of the Royal Society.

Lubrication Technique

EXPERIMENTS for determining both the qualities and methods of application of lubricants are sometimes vitiated by being carried out too quickly. An oil behaves quite differently, for example, when introduced in a properly run-in bearing and when used in one that has been recently assembled. A very similar case occurs with oil containing colloidal graphite. This oil when used in a short-duration test may give results which are misleading. It is claimed by the manufacturers of a product of this nature, Messrs. E. G. Acheson, Ltd., Thames House, Millbank, London, S.W.1, that the particles of graphite in colloidal suspension form a slippery surface on the working faces of the parts in contact, but that, due to the stable nature of the lubricant, an appreciable time may be required for the particles to become adsorbed on the surfaces. Research has shown that the rate of adsorption on a metallic base depends, to a great extent, on the viscosity and chemical nature of the carrier, this rate being low for oil of average viscosity and high for water, which has a relatively low viscosity.

Confirmation of this finding may be found in a paper by Messrs. Fogg and Hunwicks, entitled "The Static Friction of Lubricated Surfaces", published in the *Journal of the Institution of Petroleum Technologists* of January. To facilitate comparative tests, Messrs. Acheson have now developed a technique to which they have given the name 'pre-lubrication'. This consists simply of forming a graphite coating or film on the working surfaces prior to assembly, by spraying or brushing colloidal graphite on to them, the graphite being applied, in this case, in a volatile carrier such as carbon tetrachloride, white spirit or acetone. The rapid evaporation of the carrier leaves a lubricating graphited surface, thicker, naturally, than one deposited during normal lubrication, but functioning in much the same way. The formation of the initial film does not eliminate the necessity for using colloidal graphite in the lubricating oil during the normal running-in period, and afterwards if desired, since the graphited surface requires renewal from time to time.

Mammals and Man

REFERENCE was made in NATURE of Feb. 22, to the temporary exhibition "Mammals and Man" at the National Museum of Wales, and to the lack of references in the guide-book "to modern developments such as the varied and most important uses of whale oil, the increasing resort to mammal products in biological therapy", etc. Mr. Colin Matheson, curator of the Museum, informs us that a well-known British firm has provided samples of vitamin A concentrate prepared from whale liver, hydrogenated whale oils of various melting points, spermaceti, and other important cetacean products, for the exhibition. The exhibit was unfortunately delayed in transit owing to war conditions, and did not arrive until the guide-book was in the press.

William Withering

MARCH 17 marks the bicentenary of the birth of Dr. William Withering, who was celebrated alike as physician, botanist and mineralogist. He was born at Wellington, Shropshire, the only son of Edmund Withering, a surgeon. He received his medical education at Edinburgh, where he qualified in 1776 with a thesis on "Malignant Putrid Sore Throat", which he afterwards identified with a severe form of scarlet fever. After a visit to Paris, where he attended a meeting of the Royal Academy of Sciences, he settled in Stafford in 1767 and first began to collect flowers. In 1775 he moved to Birmingham, where he soon acquired a lucrative practice, and the following year published his most important work entitled "A Botanical Arrangement of all the Vegetables naturally growing in Great Britain". The book went through seven editions, and an abbreviated version, of which three were published, by W. Macgillivray, first appeared in 1830.

At Birmingham Withering became a member of the Lunar Society, so called from its monthly meetings, and made there the acquaintance of Priestley, Watt and other distinguished men of science. In 1779 he published his "Account of the Scarlet Fever and Sore Throat, particularly as it appeared in 1778–1779", which is an important contribution to epidemiology and clinical medicine. In 1785, when he was elected F.R.S., appeared his classical paper on the foxglove, the value of which in dropsy he had learnt from an old woman in Shropshire, an excellent example of a folk-lore remedy being adopted by the orthodox profession. His interest in mineralogy is shown by the several contributions to the *Transactions of the Royal Society*. He also translated and annotated a treatise entitled "Outlines of Mineralogy" by Bergman "(1783). During a visit to Lisbon in 1795 he wrote a paper on "A Chymical Analysis of the Water at Caldas da Rainha, in Portugal", which he presented to the Royal Academy at Lisbon, for which he was admitted a foreign corresponding member.

His name has been given to the mineral known as 'witherite', consisting of barium carbonate, which he recognized to be distinct from baryta, as well as to the genus of Solanacea (*Witheringia Solanacea*). In 1792 he contributed a paper entitled "A Method of preserving Fungi, ascertained by Chymical Experiments" to the *Transactions of the Linnean Society*, of which he was elected a fellow the following year. He died on October 6, 1799, and was buried at Edgbaston, where the church contains his monument with a represensation of a foxglove on the right and of *Witheringia Solanacea* on the left.

Announcements

THE following promotions and transfers have recently been made in the Colonial Service: J. D. Broatch (agricultural superintendent), senior agricultural superintendent, Gold Coast; D. H. Brown (agricultural officer), senior agricultural officer, Nigeria; T. A. Buckley (chemist), senior chemist, Malaya; K. T. Hartley (chemist), senior chemist, Nigeria; L. J. Packham (agricultural superintendent), senior agricultural superintendent, Gold Coast; L. S. Davis (assistant Government analyst), Government chemist, Trinidad; E. J. Strugnell (senior assistant conservator), conservator of forests, Malaya; Dr. C. M. Tattam (geologist), senior geologist, Nigeria.

MESSRS. OLIVER AND BOYD LTD., Tweeddale Court, Edinburgh, and 98 Great Russell Street, London, W.C., have been appointed publishers to the Royal Society of Edinburgh. Copies of previous issues of the *Transactions* and *Proceedings* and of all future publications of the Society will now be supplied by this firm.

THE Canberra Experiment Station of the Plant Industry Division of the Australian Council for Scientific and Industrial Research is to be removed to a new area to the north of the capital, about four miles from the laboratories at Black Mountain. The area is eight hundred acres, of which six hundred are red and grey loams and the remainder rather lighter. The site is ideal for experimental work, and it should be possible in time to develop on it a first-class investigation centre.

ACCORDING to the seventeenth annual report of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation, eighty-one applications for grants were received by the trustees, and twenty-three grants were made. In the seventeen years of its existence the Foundation has made three hundred and ninety-four grants, which have been distributed to investigators in most countries of the world. For the present, researches are being favoured that are directed towards the solution of problems in medicine and surgery or in branches of science bearing on medicine and surgery. Grants may be used for the purchase of apparatus and supplies that are needed for special investigations. The maximum grant will usually be less than 500 dollars. Applications for grants to be held during the year 1941–42 must be in the hands of the Executive Committee before April 1941. Applications should be sent to Dr. Joseph C. Aub, Collis P. Huntington Memorial Hospital, 695 Huntington Avenue, Boston, Massachusetts, U.S.A.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*

In the present circumstances, proofs of "Letters" will not be submitted to correspondents outside Great Britain.

Nicotinamide, Cozymase and Tissue Metabolism

The importance of cozymase as a fundamental constituent of certain respiratory processes in the living cell is now well established. It is known that cozymase is necessary for the activity in animal tissues of specific dehydrogenases oxidizing alcohol, lactate, malate, triosephosphate, etc. Its mode of action is reasonably clear. After combination with a dehydrogenase, it is reduced by a substrate (for example, lactate) with the formation of reduced cozymase and the oxidized product of the substrate (for example, pyruvate). The reduced cozymase is oxidized to its original form by other enzyme systems in the cell, transfer of hydrogen from the substrate to the final oxidizing agent being thus accomplished. Cozymase acts as a catalyst in the transfer of hydrogen in the cell, and in the intact tissue a dynamic equilibrium between reduced and oxidized cozymase is presumably always maintained.

Whilst carrying out investigations into the respiratory activity of tissues damaged by breaking up the cell structure we have found that such tissues (for example, brain, liver, kidney) possess an agent which breaks down cozymase at a rapid rate. The brain in particular is rich in this factor, as will be seen on examining the typical results shown in Table 1.

Table I

Lactic dehydrogenase system consists of a mixture of skeletal muscle lactic dehydrogenase, heart muscle flavoprotein, sodium lactate solution (0·13 *M*.), sodium cyanide (0·083 *M*.) and methylene blue (0·017 per cent) in phosphate buffer (0·02*M*.) *p*H 7·4. Brain preparation consists of a suspension of finely ground rat brain (1 gm. to 10 ml. saline).

	Oxygen uptake at 37° in 1 hour
Lactic dehydrogenase system	24·0 c.mm.
+ cozymase (1 mgm.)	205·2 „
+ cozymase + 0·2 ml. brain preparation	108·9 „
+ cozymase + 0·4 ml. brain preparation	64·0 „
+ cozymase + 0·1 per cent nicotinamide	195·9 „
+ cozymase previously incubated for 15 min. at 37° with 0·2 ml. brain preparation	54·1 „
+ cozymase previously incubated for 15 min. at 37° with 0·2 ml. brain preparation + 0·1 per cent. nicotinamide	167·2 „

These observations show that the addition of a small quantity of a suspension of finely ground brain tissue to a system containing lactic dehydrogenase, cozymase, flavoprotein and lactate greatly diminishes the rate of oxidation of the lactate. This diminution of activity is due to the breakdown of cozymase by the brain suspension. This is shown (see Table 1) by adding to the lactic dehydrogenase system a cozymase preparation which had been incubated for a short period with a small quantity of brain suspension. Such addition leads to little or no increased respiratory rate, in contrast to that which takes place when cozymase alone is added to the system. It may be shown, too, that the inhibiting action of a small quantity of brain suspension on cozymase activity applies not only to the lactic dehydrogenase of rabbit skeletal muscle (results of which are given in Table 1) but also to that of a rat kidney preparation (see Tables 2 and 3). A result given in Table 2 shows that the factor present in brain which inactivates cozymase is also present in liver, and we have evidence to show it is present in kidney, though in smaller amount. Further evidence has been secured which shows that the inactivation of cozymase by tissues may take place under strictly anaerobic conditions and we conclude, for the time being, that the inactivation is due to a hydrolysis of cozymase by a nucleotidase.

Table 2

Kidney system consists of a suspension of finely ground rat kidney tissue (1 gm. to 10 ml. saline), sodium cyanide (0·083*M*.) and methylene blue (0·04 per cent). Liver preparation consists of a suspension of finely ground rat liver (1 gm. to 10 ml. saline).

	Oxygen uptake at 37° in 1 hour
Kidney system + sodium lactate (0·13 *M*.)	59·9 c.mm.
+ cozymase (1 mgm.)	189·4 „
+ cozymase + 2 ml. brain suspension	58·5 „
+ cozymase previously incubated with 0·2 ml. liver preparation	57·8 „

Table 3

	Oxygen uptake at 37° in 30 min.
Kidney system + sodium lactate (0·13 *M*.)	
+ cozymase (1 mgm.)	66·0 c.mm.
+ cozymase + nicotinamide (0·1 per cent)	89·8 „
+ cozymase + 0·2 ml. brain suspension	10·5 „
+ cozymase + 0·2 ml. brain suspension + nicotinamide (0·1 per cent)	77·1 „

It is evident that, since brain tissue contains a most active cozymase nucleotidase, rapid synthesis of cozymase must take place in intact brain tissue examined under optimal respiratory conditions in order to balance the nucleotidase activity and to account for the maintenance of oxidative activity of brain when this is allowed to respire *in vitro* in a lactate medium. (Alternatively it must be concluded that cozymase nucleotidase is ineffective in intact animal tissues under aerobic conditions.) Hence there must exist in intact tissue an equilibrium between the mechanisms responsible for synthesis of cozymase and those responsible for its breakdown. The existence of this equilibrium probably accounts partially for the fact that the respiration of minced or ground tissues is often much lower than that of intact tissues; in the former tissues synthetic mechanisms are impaired, probably by loss of cell constituents by diffusion, etc.

We decided it would be of interest to discover how the cozymase nucleotidase activity of ground tissues could be inhibited. We have found that nicotinamide

—a constituent of cozymase—brings about such an inhibition. Results given in Table 1 show that if cozymase is incubated in presence of a small quantity of brain suspension together with 0·1 per cent nicotinamide, very little breakdown of the cozymase takes place. Results given in Table 3 show the stimulating action of nicotinamide on the oxygen consumption, when this is added to a kidney preparation of lactic dehydrogenase to which cozymase and brain suspension have also been added. The effect of nicotinamide on the activity of brain tissue itself, in the presence of lactate and cozymase, is shown in Table 4, where typical results obtained by the technique of Quastel and Wheatley[1] are given.

TABLE 4

Brain system consists of 1 ml. brain suspension (1·6 gm. chopped rat brain in 16 ml. Locke solution), cozymase and sodium cyanide (0·05 *M.*) in bicarbonate-Locke medium (*p*H 7·4). Sodium ferricyanide (0·2 ml. 10 per cent) was added, in an atmosphere of 95 per cent nitrogen + 5 per cent CO_2, and the evolution of CO_2 measured.

	CO_2 output at 37° in 1 hour
Brain system	85·6 c.mm.
+ nicotinamide (1·0 per cent)	85·6 ,,
+ sodium lactate (0·13 *M.*)	107·5 ,,
+ sodium lactate (0·13 *M.*) + nicotinamide (1·0 per cent)	357·8 ,,

These results make it clear that nicotinamide exerts an inhibitory effect on the breakdown of cozymase by a tissue nucleotidase. A few experiments have indicated considerable specificity of nicotinamide in this respect. Nicotinic acid at the concentrations we have used has no effect. It would not be expected that nicotinamide would effect any stimulation of the respiration of intact tissues obtained from healthy animals since in such tissues the breakdown of cozymase is balanced by its synthesis. Experiment shows that 0·1 per cent nicotinamide does not increase the respiration of intact brain slices in a lactate medium. There is, on the contrary, a small inhibition of the respiration such as has already been reported by Baker, Fazekas and Himwich[2].

This demonstration of the action of nicotinamide in protecting cozymase from breakdown, possibly by competition for the nucleotidase, raises the question as to whether the well-known therapeutic effects of nicotinamide may not be due partly to this action. If this view is true, substances other than nicotinamide having a similar protective effect may have similar therapeutic effects. It is interesting to note in this connexion that Vilter and Spies[3] have shown that quinolinic acid will cure pellagra and that Wooley *et al.*[4] find that a variety of nicotinic acid derivatives will cure canine black tongue. Moreover, as a result of the administration of quinolinic acid there has been found[3] an increase in concentration of cozymase in the blood.

Work on this problem is still in progress and further details will be published in due course.

We are grateful to the Rockefeller Foundation and to the Medical Research Council for financial help.

Rates of Oxidation of Isomeric Dihydroxy- and Tetrahydroxy-stearic Acids by Lead Tetra-acetate

MEASUREMENTS of the rate of consumption of lead tetra-acetate, when used in strictly comparable conditions to oxidize various isomeric polyhydroxystearic acids, have revealed marked differences between the speed of oxidation of isomeric forms. We have observed these differences both in the two isomeric 9, 10-dihydroxystearic acids (m.p. 95° and 132°) and in the four known forms of 9, 10, 12, 13-tetrahydroxystearic acids (m.p. 173°, 163°, 146° and 134°). Further measurements are in progress in the group of tetrahydroxy-acids, and the complete results of this work will be reported in fuller detail later.

The data in the accompanying table show the rate of oxidation of the two 9,10-dihydroxystearic acids when each (0·0005 mole) was oxidized in glacial acetic acid (100 ml.) containing lead tetra-acetate (0·001875 mole) at 20°:

Time (min.)	Moles lead tetra-acetate consumed per mole dihydroxystearic acid	
	Acid m.p. 95°	Acid m.p. 132°
0·5	1·23	0·10
1·5	1·48	0·18
2·5	1·60	0·27
3·5	1·64	0·37
4·5	1·70	0·45

100	1·97	1·72
160	2·01	1·80

The rate of oxidation of the acid, m.p. 95°, is far more rapid than that of the isomeric form, m.p. 132°. The difference in the rate of oxidation of the two acids is similar to that of many pairs of cyclic glycols; Criegee[1] has shown, in the case of the latter geometrical isomerides, that *cis*-glycols are attacked by lead tetra-acetate more rapidly than the *trans*-isomerides. In the acyclic polyhydroxystearic acids, however, the stereoisomerism is that of two (racemic) asymmetric carbon atoms, and is not a case of geometrical isomerism.

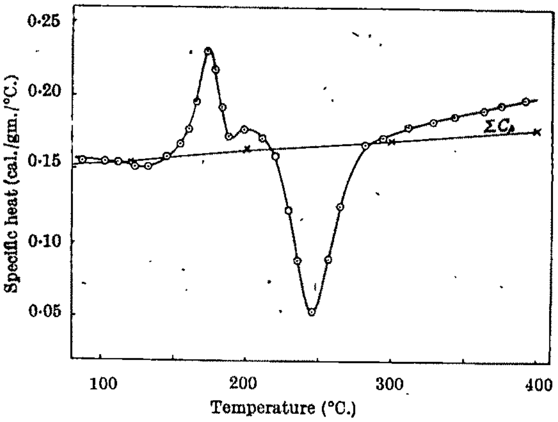
Pre-Precipitation Phenomena in Age-Hardening Alloys

USING an improved X-ray technique, Preston[1] and Guinier[2] have shown that when aluminium-copper single crystals containing 4 per cent copper are aged at low temperatures, thin plates of copper-rich atoms are formed on (100) planes of the crystal. Swindells and Sykes[3] found, from specific heat measurements on a similar alloy, that when specimens previously aged at low temperatures were re-heated, heat was absorbed before the chemical energy of precipitation was liberated. They suggested that this energy absorption was due to the dispersion of the copper-rich plates formed during the low-temperature ageing, an interpretation which was confirmed by Preston.

The fact that no change is observed in the lattice spacing of the crystal as a whole, even though nearly half the energy of precipitation may be released by the low-temperature ageing, suggests that the segregation of copper atoms is largely on the solid solution lattice, or in other words the precipitate has not broken away to form separate crystals, distinct from the matrix.

Aluminium-copper was the only alloy in which such pre-precipitation phenomena had been detected by X-ray methods, but recently Barrett and Geisler[4] have observed that plates of silver-rich atoms are formed on the (111) planes of a single crystal of an aluminium-silver alloy containing 20 per cent of silver, after ageing at low temperatures.

We have determined the specific heat - temperature curve of a specimen of an aluminium-silver alloy containing 40 per cent of silver quenched from 550° C. and aged for seven days at room temperature. The accompanying curve was obtained using the method described by Sykes and Jones[5]. The line marked ΣC_p shows the specific heat of the alloy calculated from the specific heats of pure aluminium and pure silver. The specific heat - temperature curve found experimentally bears a marked resemblance to those of Swindells and Sykes on aluminium-copper and may be interpreted similarly. The energy measurements thus give some confirmation for the X-ray results of Barrett and Geisler.



Although these workers have not investigated the point, it is to be expected that what Mehl[6] calls retrogression, such as is observed in aluminium-copper alloys, would also occur in aluminium-silver alloys.

Weighing Living Marine Animals

THE substance of Dr. Gohar's letter[1] is contained in his fourth paragraph : "It is therefore possible to determine the volume and weight-in-air of such animals, excluding the water they contain, by weighing in two samples of water of different but known specific gravities". No experiments are described. The Archimedean formula is correctly stated on the assumption that the volume of the animal remains the same in the two samples of water : this can be true of few animals.

L. C. Beadle[2] experimented on the changes in sinking weight of the common polychaete worm *Nereis diversicolor* after transference from sea water to various dilutions. Nereis is a favourable subject since it is markedly euryhaline ; the specimens observed were gathered from an estuary where, with rising and falling tide, the worms changed twice a day from an environment of sea water to one diluted by river water, sometimes down to 60 per cent of its former salinity. Schlieper is quoted as having collected Nereis in water of salinity equivalent to only 12 per cent of sea water.

Beadle finds that after transference from 100 per cent to 25 per cent sea water "the weight rose to a maximum after 5–7 hours and then fell to a relatively steady value at 24–30 hours". The following extract showing separate observations on six individuals destroys any hope of measuring accurately the volume of Nereis by Dr. Gohar's method. From Table IV :

Percentage increase in weight in 25 per cent sea water, specimens *a–f* :

After	4¼ hours :	(*a*) 47 per cent	(*b*)	54 per cent
,,	22¼ ,, :	(*c*) 87 ,,	(*d*)	135 ,,
,,	50¾ ,, :	(*e*) 74 ,,	(*f*)	35 ,,

The body-fluid concentration was measured in terms of the isotonic percentage of sea water. In 100 per cent sea water this lay between 99 and 101 per cent, but in dilute environments the body-fluid was always markedly hypertonic to the surrounding medium. Thus, in the four specimens *c–f*, which had been more than 22 hours in 25 per cent sea water, the body-fluids ranged in isotony from 37 to 42 per cent sea water : that is, 50–70 per cent above the surrounding medium. No attempt can be made here to summarize Beadle's very interesting discussion of the parts played by muscular contraction, nephridial action, etc. ; it is sufficient that the experimental facts disprove Dr. Gohar's prophecy that when the salinity of the environment is changed "the existence of a physico-chemical equilibrium may be foretold".

Since sponges figure first on the list of animals for which "this method is especially suitable", I must point out that from one quarter to three quarters of the volume of a sponge consists of an intercellular jelly, often very watery, the bulk of which must be greatly affected by osmosis ; also in 1895 I figured[3] changes in form of collar-cells in response to changes of salinity and/or *p*H. Measurement shows that they are accompanied by change of volume of the cells.

In 1923 I published[4] a determination of the volume of a preserved *Leucandra aspera* hardened in alcohol. The sponge was weighed in alcohol of different strengths and in water ; I confess that this involved an error similar to Dr. Gohar's, for I now recognize that the hardened cells swell in weaker alcohols and shrink again when dehydration is repeated.

Three years ago, A. G. Lowndes published[5] a very beautiful method for obtaining the volume of living marine organisms, estimating by titration the amount of chlorides in a specific gravity bottle filled with sea water and comparing it with the amount in the same bottle filled with sea water containing a Nereis: the difference gives the amount of chlorides displaced by the Nereis and hence the volume of sea water displaced. The filled specific gravity bottle is in each case weighed, and the difference between the weights is the difference between the weights of that volume of sea water and that volume of Nereis.

Since then, Mr. Lowndes has been kind enough to show me, from time to time, the results of similar measurements in which I was interested. They are remarkably consistent and in his hands the method seems very perfect.

Symbiosis in Larval Siricidæ (Hymenoptera)

THE presence of a symbiotic basidiomycete fungus in the adult females of the woodwasp *Sirex gigas* L. was first described by Buchner[1]. Subsequent work by Cartwright[2,3] and Francke-Grossmann[4] has shown that the fungi in this and other species can exist independently and are, in fact, common wood-destroyers. Each egg as it passes into the ovipositor is coated with oidia of the fungus, which grows into the wood in advance of the tunnelling larva and may be the insect's source of food. Francke-Grossmann[4] could find no fungus in the larva, except in the alimentary canal, and decided that the immature female wasp becomes infested by hyphæ growing from the wall of the tunnel into the special intersegmental pouches very soon after the pupal skin is shed.

During a re-investigation of the whole subject, my observations on *S. gigas* L. and *S. cyaneus* F. have confirmed those of the above authors. In addition, fungus has been located in the larva in special organs arising from a modification of the integument on the posterior side of the hypopleural folds on the first abdominal segment. The cuticle is deeply pitted in a characteristic way, and the underlying hypodermal cells are greatly enlarged and probably have a special secretory function. In sections, the fungus can be clearly seen in the pits. The organs were found in a proportion of the larvæ corresponding approximately to the sex ratio of the adults and pupæ cut from the same section of log, suggesting that they are present in female larvæ only. The fungus in these larval organs has been isolated into pure culture and found to be *Sterum sanguinolentum* (A. and S.) Fr.; this species has been shown by Cartwright to be present both in larval tunnels and the intersegmental pouches of the adult female woodwasp.

The significance of these organs in the larvæ has yet to be explained, particularly in relation to the absence of fungus from the pupal stage of the insect. The problems of the part they play in the symbiotic cycle and of their fate during ecdysis are extremely interesting, since the structures are external. The work has now had to be suspended, but an account of the progress to date is being prepared for publication elsewhere.

Staining of Bacteria and Certain Fungi

THE usual method for staining bacterial and yeast spores requires three operations: the staining of both spores and vegetative cells by applying heat to the slide bearing the dye; the removal of stain from the vegetative cells with a decolorizing agent; and counterstaining the vegetative cells with a dye of a different colour. The same treatment is used to differentiate acid-fast bacteria from others.

A solution has been developed for staining spores and vegetative cells differentially in one operation. Fixed films of bacteria or yeasts are stained for one minute over steam with a solution consisting of malachite green 0·5 per cent, basic fuchsin 0·05 per cent, in distilled water; the film is then washed and dried. Spores are stained greenish blue, other cells violet or, in older cultures, pink. Acid-fast bacteria retain the greenish-blue tinge, and may show the presence of violet granules; all non-acid fast bacteria so far tested are stained violet.

A saline dilution of the staining solution has been developed especially for differentiating the hyphæ and conidia of certain fungi in agar plate cultures.

A paper giving other details will shortly appear in the *Canadian Journal of Research.*

RESEARCH ITEMS

Hungarian Throwing Sticks

POSSIBLE ethnological affinities for a 'casting staff' in use in Hungary some thirty to forty years ago have been suggested by Béla Garda, of the Ethnographical Museum, Budapest (*Man*, Jan. 1941). The Hungarian casting staff was a characteristic weapon of the herdsmen, who were never without them. They were used in fights among the herdsmen themselves or against wolves attacking their herds. Cattle thieves also employed them to drive off anyone attempting to intercept them on their marauding expeditions. The casting staff was a rounded wood cudgel, 65 cm. long and 5 cm. in diameter and pointed at each end, the points being hardened by fire. In throwing, it was held at one end, and it was effective up to 50–100 paces. It appeared first on the Greater and Minor Kunsag of the Hungarian plateau, where a pastoral life was the characteristic condition. Literary references to it are found from the fifteenth century onward. This throwing staff is entirely different from the throwing sticks and boomerangs of European prehistoric and later times. An identical form, however, is found in the Malay Peninsula, in Borneo and Marshall, Gilbert and Yap Islands. Zs. Bátky, the Hungarian ethnologist, is of the opinion that the Hungarian weapon was brought by the Hungarians from the East, its ancient home being the great steppe lands of Asia. In support of this, it is here pointed out that the social organization and civilization of the Hungarian herdsmen show the marked eastern character of the horse-nomads. It is possible, therefore, that the connexion between the casting staves of Hungary and Indonesia-Micronesia may be placed in the same great prehistoric-ethnological culture-frame to which belong the conformities of the Asiatic nomad cultures and of the Oceanic culture of the Farther Indies.

Saxon Relics from Lincolnshire

St. Peter's Church at Barton-on-Humber, North Lincolnshire, one of the oldest churches in England, dates in part from Saxon times; but up to the present, little evidence has been obtained as to the people by whom it was first built. Recent excavations for an air-raid shelter brought to light two or three human skeletons and some pieces of metal which were handed to T. Sheppard of the Hull Museum, by whom the site was visited, and these and later finds are now described (*Hull Mus. Pub.*, No. 208; 1940). It was evident that a number of Anglo-Saxons had been buried just below the original surface, which at a later date had been covered by 5–6 ft. of boulder clay. The bones showed that one body was that of a woman, while another was that of a man of large proportions aged about 45 years. The most interesting find was a large thin bronze bowl with three escutcheons with hooks, each fastened with three bronze rivets; otherwise it is devoid of decoration. It is comparable with other bowls of this type found with Saxon remains, but which T. D. Kendrick has assigned to a Romano-British or British origin. Remains of a trivet with two feet suggest the deposit at Barton of a second bowl of the trivet stand type, but the bowl itself has not been found. Another interesting object was a cylindrical bronze box with a bronze loop, presumably for attachment to a lady's chatelaine. Such boxes were used for carrying sewing or other materials. A long gold bead is unique among Anglo-Saxon gold beads. Extension of the excavation raised the number of skeletons to five in all, and produced a very fine short sword, a set of scales and weights, remains of a bone comb, a large decorated bronze handle and a heavy curved piece of bronze. The scales consist of two plain pans, slightly concave, each 2⅛ in. in diameter, and each perforated for three bronze rings for suspension. The balance beam is of circular bronze wire 5 in. long with zoomorphic terminals, such as have not previously been recorded on balance beams. Beneath each terminal is a loop containing a small bronze ring. From the centre rise two upright pieces of bronze 2 in. in length. Swinging between the two is a pointer of bronze 1 in. in length. Four metal weights ranged from 200·4 grains down to 95·9 grains; other pieces of metal and a Roman coin presumably used as weights from 39·9 grains down to 8·7 grains. A few days after the find of a hanging bowl at Barton, a similar bowl was found at Manton Common, Lincs, while a fine example was found at Caistor in 1857.

Minor Plant Diseases

W. C. MOORE has described three minor plant diseases (*Trans. Brit. Mycol. Soc.*, 24, Pts. 3 and 4, 345–351; Dec. 1940). An angular leaf spot of the apple, previously attributed to the fungus *Phyllosticta angulata* and another species, is now shown to be initiated by an insect, the frog-hopper *Cercopsis sanguinea*. The fungi are there as secondary parasites, but only serve to accentuate a malady already present on the foliage. Leaf spot of lettuce, caused by *Septoria lactucæ*, was observed in Harpenden during the summer of 1940. Infected plants formed hearts, but were very unsightly. Colchicum plants are subject to attack by the fungus *Pythium ultimum*, which is also the cause of watery wound rot in Duke of York potatoes and a rot in tulip bulbs. The disease in Colchicum appears usually during the summer, and indeed some corms are completely disorganized when lifted. Pathogenicity has been established by inoculation with pure cultures.

Origin of Secondary Trisomics

M. M. RHOADES (*Genetics*, 25, 483–520; 1940) has provided cytogenetical evidence that a secondary trisomic involving chromosome 5 of maize arose from an abnormal chromosome which consisted of one arm of chromosome 5 and therefore had a terminal centromere. This terminal centromere is shown to be unstable both in meiosis and mitosis. Transverse division of the centromere during the first microspore division would give a chromosome with a median centromere and two identical arms. Cytogenetical evidence is given of the mode of disjunction in a trivalent and of the linkage group 72 units in length involving 8 genes.

Experiments in Selection

The number of hairs on the ventral surface of the fourth and fifth abdominal segments are inherited as polygenic characters in *Drosophila melanogaster*. K. Mather (*J. Gen.*, **41**, 159–194; 1941) subjected the F_2 of certain crosses to selection for the number of such hairs. In one cross, the greatest change in hair number took place in the first two selected generations. In another cross involving two different stocks, an advance with selection took place in the first two selected generations, followed by a period of stability which was again followed by a considerable advance. By intercrossing the inbred selected lines a greater variation was found in their F_2 as compared with that of the original F_2. This is interpreted to mean that the first advances are due to recombination of independent genes and the second to recombination of linked genes. This presupposes the existence of a balanced combination of genes controlling polygenic characters in one chromosome. Such linked genes will be favoured by natural selection, since the mean expression of a selected variable character will almost coincide with the optimum in the population. Stability of this mean is necessary in the present environment and is achieved by linkage, whereas ability to vary with changing environment is necessary for evolution and is brought about by crossing-over by linked genes. The author therefore accounts for clines in wild populations.

Estimation of Carbon Dioxide in Air

A new method of estimating small quantities of carbon dioxide in air by the absorption of infra-red radiation is described by H. Dingle and A. W. Pryce in *Proc. Roy. Soc.*, B, **129**, 468–474 (1940). Older methods of making this measurement, which is of considerable importance in plant and animal physiology as well as in chemistry, depend on chemical processes or on measurement of the electrical conductivity of solutions in which the carbon dioxide is absorbed. In 1937, however, McAlister introduced a spectrometric method, in which the amount of carbon dioxide was estimated directly from the amount of absorption, by the air under examination, of infra-red radiation near $4\cdot3\,\mu$, the maximum of a strong absorption band of carbon dioxide. The radiation, after passing through the air, was received by a spectrometer set at this wave-length. Dingle and Pryce, however, show that the spectrometer is unnecessary if the air is dried, since the only atmospheric gases which absorb radiation in the near infra-red are carbon dioxide and water vapour. It is therefore necessary merely to compare the total radiation from a bunsen burner transmitted by the air under examination, with that transmitted by a standard quantity of dry air free from carbon dioxide, in order to determine the amount of carbon dioxide present. The amounts of radiation transmitted by the two samples of air fall on two thermopiles connected so that the galvanometer shows the difference in the currents produced. In addition to its greater convenience, this method has three advantages over the measurement at the maximum of the absorption band; it eliminates the cost of the spectrometer, it gives much greater sensitivity since the whole of the transmitted radiation is used, and it is much less affected by variations of temperature, which change the position of the absorption band but do not greatly alter the total absorption.

Surface Effect in Slow Combustion of Hydrocarbons

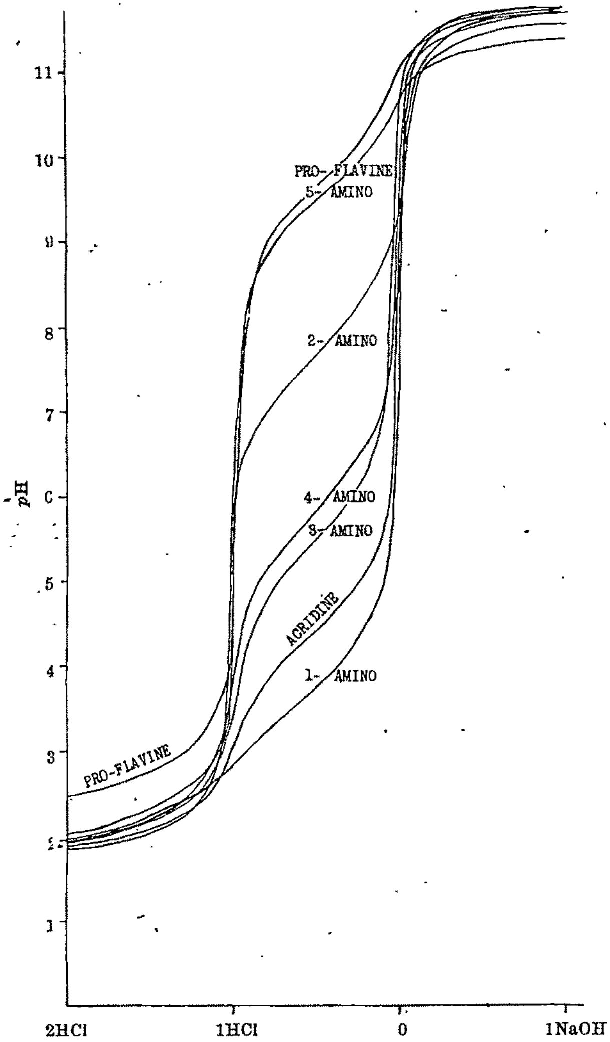
A systematic study has been made by R. G. W. Norrish and J. D. Reagh (*Proc. Roy. Soc.*, A, **176**, 429–48; 1940) of the effect of surface on the slow oxidation of several hydrocarbons, both saturated and unsaturated. Special reaction vessels of approximately constant volume but widely varying diameter were used. All reactions were of the degenerate branching type, and were found to be principally homogeneous in character. When the diameter of the reaction vessel was sufficiently reduced, the reaction rate fell abruptly towards zero, whilst the corresponding induction period increased towards infinity. In narrow vessels, surface deactivation can predominate over other processes of deactivation. In wider vessels, surface and volume deactivation occur to a comparable extent over a considerable range of pressure. The surface deactivation almost alone can suppress the factors leading to chain branching when the vessel diameter is decreased to a critical value. From the reactions studied, the occurrence of this critical diameter appears to be general for hydrocarbon oxidation, in conformity with the theory of degenerate branching.

Motion of Solar Prominences in Three Dimensions

The application of kinematography to the spectrohelioscope has given us, during the past few years of solar activity, some spectacular motion pictures of solar prominences. Outstanding among the institutions engaged in this fascinating work is the McMath-Hulbert Observatory on Lake Angelus, Mich. A further development is now reported from this station (*Publ. Obs. Univ. Mich.*, **8**, 57; 1940): a new spectroheliograph has been designed to give a continuous record of the line-of-sight motions of solar phenomena, particularly of prominences at the limb. The instrument differs from an ordinary spectroheliograph only in the motions executed by the slits in making the record. The first slit is narrow, as is an ordinary entrance slit, and during the recording it scans the prominence image and the adjacent sky intermittently at positions separated by 2 mm. intervals. The second slit is 2 mm. wide and limits the length of the spectrum recorded on the film to 1 mm. on either side of (say) the $H\alpha$ line, which appears in absorption in the light of the sky and in emission in the prominence. The intermittent motion produces a series of such strips placed end to end, and the grid of absorption lines so formed is used to detect at various points in the prominence those displacements of the emission line which are characteristic of line-of-sight motions. In order to facilitate identification of the feature whose radial velocity is being recorded, the wide second slit is automatically narrowed after the intermittent exposure, and a continuous scan then superposes a faint prominence picture on the grid of absorption lines. The whole cycle is then repeated with the first slit moved on, with respect to the solar image, by its own width; and so on until the whole 2 mm. is covered. No part of the prominence, then, can escape the intermittent scan, and on completion of twenty such cycles, a record of the radial velocity at all points on the image has been obtained. Correlation of such records with conventional spectroheliograms taken simultaneously will give three-dimensional pictures which cannot fail to add considerably to our knowledge of prominence motions.

CORRELATION OF BASICITY AND ANTISEPTIC ACTION IN AN ACRIDINE SERIES

THE amino acridines are unique among antiseptics in combining a high bacteriostatic activity in the presence of tissue fluids with a relative innocuousness to leucocytes. Hence any information that relates their physical and chemical properties with their antibacterial action is of general interest. The effect on bacteriostatic activity of varying the positions of amino groups in the acridine nucleus has already been studied in a series of *di*aminoacridines[1] which included the widely used antiseptics proflavine (2 : 8-diaminoacridine) and acriflavine. The contribution of each amino group towards the total effect was therein assessed, thus virtually predicting the antiseptic properties of the five isomeric *mono*-aminoacridines.



POTENTIOMETRIC TITRATION CURVES OF ACRIDINE AND DERIVATIVES

These five monoaminoacridines have now been examined for their antiseptic activity and the results correspond to those predicted. It is noteworthy that two of these simpler monoamines are approximately equal in bacteriostatic effect to the best of the diamines (for example, proflavine).

Further, potentiometric titration of these bases now reveals a remarkable correlation between their strength as bases and their antiseptic activity, the one increasing with the other. The results of these experiments, in which acridine and proflavine have been included for comparison, are condensed in the accompanying table and graph.

These figures represent the highest dilution inhibiting growth after incubation at 37° C. for forty-eight hours (when growth took place in No. 1 dilution, '0' was recorded). All experiments were carried out, in duplicate, according to the method of Garrod[1], which was extended to a wider variety of organisms. The streptococcus was a highly virulent Group A type, the *Staphylococcus aureus* was freshly isolated from a human infection and the *Clostridium Welchii* from a case of gas-gangrene. The latter organism proved the most susceptible of those tested, streptococcus, staphylococcus, *B. coli* and *proteus* following in that order, thus demonstrating a greater activity against Gram-positive types (cf. Browning[2]).

The titrations shown in the graph were carried out at 20° C. by running $N/1$ hydrochloric acid followed by $N/1$ sodium hydroxide into 30 mils of a solution of 0·0005 gm. mol. of the base in 67 per cent methanol.

CORRESPONDENCE BETWEEN BASICITY AND ANTISEPTIC ACTION

Substance	Medium : Broth *p*H 7·4					Medium : 10% serum-broth *p*H 7·2					Bacteriostatic Index (sum-total of inhibitory dilutions)	*pK* in water*	*pK* in 67% aqueous methanol*

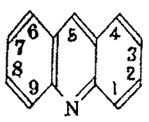
* *p*K represents—log. acidity constant (K). $K = \frac{(B)\,(\mathrm{H}^+)}{(B\mathrm{H}^+)}$

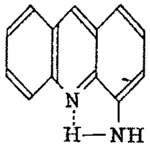
Key to Dilutions : 1 = 1 gm. antiseptic in 5,000 ml. of medium. Similarly, 2 = 1 in 10,000 ; 3 = 1 in 20,000 ; 4 = 1 in 40,000 ; 5 = 1 in 80,000 ; 6 = 1 in 160,000 ; 7 = 1 in 320,000 and 8 = 1 in 640,000.

s solution was contained in a beaker fitted with rer, glass electrode and KCl-agar bridge connected a calomel-half-cell, and a Leeds and Northrup iversal pH potentiometer assembly. Similar results ere obtained when water replaced methanol, but, wing to the base being in suspension, some difficulty was experienced in reaching equilibrium within reasonable time. The acidity constants, calculated rom both sets of results, are compared in the table. It will be seen that, with increasing strength of base, there is a progressive increase in bacteriostatic activity. It appears likely that proflavine and 5-aminoacridine are as strong bases as is desirable, since we have observed that a number of more basic diaminoacridines are equal or inferior to these.

Finally, we have attempted to correlate these great variations in basicity of a series of isomerides with their molecular structure. Acridine, the dissociation constant of which has not been previously recorded ($3{\cdot}4 \times 10^{-10}$ at 20° in 67 per cent methanol; 2×10^{-10} in water) is seen to be a base of similar strength to aniline ($5{\cdot}2 \times 10^{-10}$ at 25° in water) and forming a natural series with quinoline ($1{\cdot}1 \times 10^{-9}$ at 25°) and pyridine ($2{\cdot}4 \times 10^{-9}$ at 25°). The increased basic strengths of 3- and 4-aminoacridines compared to acridine appear reasonable for the addition of an amino group, whilst the reduced strength of 1-aminoacridine is attributed to hydrogen bonding:

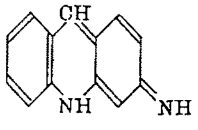


Acridine

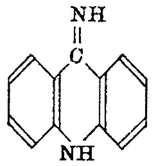


1 Aminoacridine

On account of the remarkably high basicity of the 2- and the 5-aminoacridines, it is preferable to represent these as the tautomeric acridonimines, as follows:



2–Aminoacridine



5 Aminoacridine

and this is consonant with the considerably greater basicity of the imino group compared to the amino group in the guanidine, thiourea, auramine and triphenylmethane series[3]. It is interesting to note that 4-aminopyridine (identical with the middle ring of 5-aminoacridine) is much more basic ($K = 1{\cdot}3 \times 10^{-5}$) than its isomerides[4].

ELECTRIC DISCHARGE LAMPS

DR. CLIFFORD C. PATERSON, director of the Research Laboratories of the General Electric Company, Ltd., has written an interesting review of the technical progress made last year in the development of electric discharge lamps (*Electrician*, Jan. 31). Last year he directed attention to the new problems which the 'black-out' has raised so far as general outdoor and shop-lighting are concerned. Except in special instances, these problems offer little scope for discharge lamps. On the other hand, the intensification of the War, while making these outdoor lighting (or darkening) problems more acute, has also created a greater need than ever for high efficiency light sources for our factories and workshops—a need which the existing discharge lamps go a long way to meet.

Mains voltage tubular fluorescent lamps, which follow naturally on the high-voltage fluorescent tubes in use in Great Britain since 1933, were introduced in the United States two years ago, and the demand last year reached several million lamps. The American lamps are made in a range of wattages and colours, particulars of which are given in the following table. The stated efficiencies are high, being 38 L./w. for the 30 w. daylight colour and 45 L./w. for the 30 w. white.

Dr. Paterson gave a general description of these lamps in his review last year, when their introduction in Great Britain was foreshadowed. Although the main programme on tubular fluorescent lamps has been held up in Great Britain until after the War, a special lamp to meet the requirements of war-time industry was put on the market early last year. This lamp, which is rated at 80 w., is 5 ft. long and $1\frac{1}{2}$ in. in diameter. The quoted average life is 2,000 hours, by which time the efficiency has fallen to about 70 per cent of its initial value of 35 L./w., due to the action of the mercury vapour discharge on the fluorescent coating.

U.S.A. MAINS VOLTAGE, TUBULAR, FLUORESCENT LAMPS

Lamp wattage	Length (in.)	Diameter (in.)	Colours
15	18	1	Daylight, white, blue, green, pink, gold, red.
20	24	$1\frac{1}{2}$	
30	36	1	
40	48	$1\frac{1}{2}$	Daylight, white.

The introduction of the new fluorescent lamp is a step of real importance for the illumination engineer and the public alike. A condenser of about 0·05 mfd. is placed across the lamp to prevent radio interference. The power factor correction condenser has a capacity of about 0·75 mfd. and gives an overall power factor of about 90 per cent. When the supply voltage is first switched on by closing the mains switch, the starting switch, which is either thermally or magnetically operated, short-circuits the lamp and allows the filamentary electrodes to heat up. The starting switch then opens automatically, inducing a momentary voltage kick across the lamp high enough to start the discharge.

The tube when alight has a creamy white appearance, the brightness being about 0·5 candles per sq. cm. The colour of the light, which is determined by the fluorescent coating, has been chosen very carefully to give an effect approximating to noon sunlight; the colour-rendering properties are excellent—very much better than those of ordinary incandescent filament lamps. It is not possible to obtain satisfactory colour-rendering by the use of a single fluorescent powder, since all the known powders give bands of light with a well-defined maximum in some region of the visible spectrum, but are deficient in light from other regions. To overcome this difficulty the fluorescent coating comprises a number of different powders, selected so that the peaks of their emission bands occur in complementary regions of the visible spectrum. The proportions of the component powders present in the mixture are adjusted to give the required luminosity distribution throughout the spectrum. The increase in light output due to the fluorescent coating is about 800 per cent. This application of fluorescent powders to obtain high-efficiency sources of white light was first developed in Great Britain in connexion with high-voltage tubular lighting.

Experience gained so far indicates that the new fluorescent lamp has applications in many spheres of industry and commerce, such as fine assembly benches, inspection benches, drawing and general offices, and in any situation where high-efficiency illumination approximating to daylight in its general properties is required. A range of trough reflector fittings, suitable either for high-intensity local lighting or for general lighting from greater heights, is available for use with the lamps.

FORTHCOMING EVENTS

Monday, March 17

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 5 p.m.—Capt. Graham Rowley: "Crossing Baffin Land".

Tuesday, March 18

Royal Society of Arts (Dominions and Colonies Section) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. C. W. Hobley: "Wild Life Conservation in its Wider Aspects."

Wednesday, March 19

Institute of Chemistry (London and South-Eastern Counties' Section) and the **Institute of Physics** (London and Home Counties' Branch) (Joint Meeting), (at the Royal Institution, Albemarle Street, London, S.W.1), at 2.30 p.m.—Dr. J. J. Fox: "Infra-Red Absorption and Molecular Structure".

Thursday, March 20

Royal Society (at Burlington House, Piccadilly, London, W.1), at 2.45 p.m.—Mr. G. E. Briggs, F.R.S.: "Photosynthesis in Intermittent Illumination". Mr. E. C. Bullard and Mr. T. F. Gaskell: "Submarine Seismic Investigations."

APPOINTMENTS VACANT

Applications are invited for the following appointments o before the dates mentioned:

Principal of the Leeds College of Technology—The Director Education, Education Department, Calverley Street, Leeds (March 29).

Demonstrator in Anatomy at St. Thomas's Hospital Medic School—The Dean of the Medical School, Manor House, Godalmin Surrey (March 30).

Part-time Demonstrator in Biology—The Principal, Technic College, Kingston-upon-Thames, Surrey.

FOOD DISTRIBUTION IN WAR-TIME

THE food policy of the Government during the present War has followed three main lines : it has provided for the accumulation of stocks of certain essential commodities against siege conditions ; it has largely prevented profiteering and has achieved a reasonably equitable distribution of food by a system of rationing, by price control and by subsidizing the consumption of certain foodstuffs ; it has also, by special subsidies, as in the case of milk, and by a system of differential prices in the case of margarine, done much to ensure the adequate nutrition of the poorer groups of consumers. It is indeed probable that during the first year of war, with the increase in employment and earnings, and with little diminution in the supply of food, the general average of nutrition was as high, if not higher, than in peace. Recently, however, the position has altered, and it is doubtful if the policy which was successful in 1940 will be adequate for 1941.

The increase in sinkings which occurred in the last quarter of 1940, and the additional calls on shipping resulting from the African campaign, has entailed a revision of the food import programme. "Beef or Bardia" still holds. In consequence, we cannot expect in 1941 to live as comfortably or to eat the same kind of food as we ate in 1940 or before the War. It will be necessary to change our dietary habits, to depend less on meat and more on cereals, potatoes and the cheaper vegetable foods. But if available shipping is directed to the importation of essential foodstuffs, if each prospective cargo is considered in terms of the national health, we shall have enough to eat and remain a fit nation at the end of the War.

The matter, however, does not end with the question of maintaining supplies. The question of distribution is equally important. There must be no unfair distribution of food between income classes. As the food situation deteriorates, unrationed foods increase in importance. When scarce supplementary foods are neither controlled in price nor officially rationed, they will be mainly consumed by those who can afford to buy them. There will be no queues, but the lower income groups will go without. Poultry and canned fruit, for example, provide welcome additions to the diet of the well-to-do, but are little eaten by the poor. Restaurant meals are expensive and are mainly eaten by the rich.

In addition to the difficulty of distribution which inevitably arises in case of shortage, the 'blitz' has introduced problems of its own. When the bombing of London was at its height, too many young men and women, after spending an uncomfortable and exhausting night in a shelter remote from their homes, began their day's work on rolls and coffee because they could not afford a satisfactory breakfast. This condition, if allowed to persist, is likely to have a harmful effect on health and to hinder the national effort.

The problem of food distribution, therefore, resolves itself into ensuring that available supplies are spread over the population in accordance with needs, that the lower income groups get their fair share, and that adequate facilities are provided for feeding elements of the population whose nutrition is likely to suffer as a result of war conditions. Inequalities in distribution, which might be overlooked if other foods were plentiful, become important in a period of general scarcity, and the time appears to have arrived for a revision of the rationing system.

This revision might take one of several forms.

It might be accomplished by introducing the point system, used in Germany, in which each person is given a weekly number of points which are evaluated in terms of different foods. Such a system has, however, the disadvantage that it is highly complicated in operation, and leaves the retailer too much discretion in deciding the food value of different qualities of the same commodity.

Alternatively, a limit could be placed on the weekly *per capita* expenditure on food. The objection to this method is that its adoption might result in the rich competing with the poor for the cheaper foods. This objection has been considered invalid on the ground that, if the rich did compete for the cheaper foods, the more expensive foods would fall in price and would be available to the poor. It is, however, doubtful if this would happen. In the case of certain foods it is more likely that they would go off the market. In the case of others it is likely that the present differential in price, which occurs between, say, high-price and low-price cuts of meat, would disappear, and that the poor would pay rather more for their meat and the rich less.

On balance, it appears probable that the extension of the present system of rationing to essential commodities in short supply is likely to prove more satisfactory than a system of general rationing. In cases where the amount of a commodity to be distributed is small and unlikely to provide an adequate national ration, the introduction of alternative rations might be considered. Eggs or cheese, for example, might be purchased on the same coupon. Also the rationing system should be as flexible as possible in order to admit full advantage being taken of foods which were temporarily plentiful.

It is, however, highly desirable that rationing should be supported by an extension of the present system of providing subsidies for special classes of consumers. The milk scheme which, at certain levels of income, enables free milk to be distributed to nursing and expectant mothers and to children under five, and which provides milk at a reduced price to the same classes, and to school children, whatever the income, is an important step in social progress. The classes to which it applies could, however, be widened in dealing with the distribution of certain foodstuffs.

During war the effect of rising prices is most severely felt by families with more than three children and by the small fixed-income groups, that is, by old-age pensioners, by pensioned widows and orphans, by the unemployed, by the families of men in the Services, and by persons in receipt of public assistance.

These, together with the present beneficiaries under the cheap milk scheme, and families with more than three children, form a substantial part of the population, and are likely to suffer hardship as a result of war. It is therefore suggested that certain foodstuffs in plentiful supply might be provided by subsidy to these classes.

In practice, the subsidy might operate by permitting the purchase of a daily *per capita* allowance of specific foodstuffs at a reduced price. It could apply in the first instance to such things as potatoes, which, compared with bread on a calorie basis, are expensive, to carrots and to green vegetables. It might also be applied to jam, which plays an important part in the dietary of the poor.

The adequate nutrition of the population in war-time, as well as the equitable distribution of food, would also be assisted by providing facilities for communal or collective feeding. Already a certain amount of work has been done in supplying meals in shelters, while the Ministry of Labour and National Service has been given powers to compel the owner of a factory engaged in Government contracts, and employing more than 250 workers, to provide a work's canteen. The efforts have, however, been largely unco-ordinated and spasmodic, and a more systematic approach to the problem is required.

Apart from the obvious economies which would be effected in the cost of materials, and in labour, equipment and fuel, the communal meal enables the right kind of food to be fed to different classes of workers. It makes possible the addition in concentrated form of essential food constituents not present in the original foods.

The provision of communal restaurants near large shelters would have a beneficial effect on the health of the shelter population, while the provision of works' canteens under proper supervision would do much to ensure the adequate nutrition of the factory worker, a problem which will increase in importance as more married women are employed in industry. In the same way, a midday meal in schools would help to safeguard the health of the future generation.

It is doubtful, however, whether any scheme will develop with sufficient speed unless it obtains the more active support of the Government. This support would be most adequately given in two directions: (1) by prescribing minimum standards to be applied to collective feeding and by enforcing these standards by a competent inspectorate; (2) by training and registering staff for new canteens. The scheme might be operated partly by paid and partly by voluntary labour, and organized on a regional basis, linked up with the existing regional organizations. It would then, besides providing an immediate service, be available to undertake emergency feeding in any particular area.

PREHISTORIC COMMUNITIES OF THE BRITISH ISLES

Prehistoric Communities of the British Isles
By Prof. V. Gordon Childe. Pp. xiv+274+16 plates. (London and Edinburgh: W. & R. Chambers, Ltd., 1940). 20*s.* net.

THE study of our prehistoric antiquities has already passed through several phases. The early antiquaries of Tudor and Stuart times are perhaps the most to be envied, for they could travel the country and indulge in picturesque speculation on what they saw, untrammelled by any established body of knowledge. The later eighteenth and nineteenth centuries witnessed the development of excavation, excavation which, while it began to accumulate the factual material necessary for later scientific study, was too often little more than looting to satisfy the collector's instinct and the land-owner's vanity and curiosity. By the beginning of the present century a rickety framework of information had been put together, and the achievement of outstanding individuals such as General Pitt-Rivers already gave promise of the extraordinary blossoming of a truly scientific archæology which took place in the period between two wars. The greater part of this happy period was naturally occupied with the essential preliminary task of extending conventional history backwards by establishing a fixed chronology, tracing invasions, the development of cultures and their interactions. But latterly a new trend was evident. Excavation had become sufficiently widespread, exact and selective to enable some archæologists to be less purely historical and more generally sociological in their approach. Attention began to be focused on the manner of prehistoric life, the structure of early societies, their economic basis and the density of their populations.

Prof. Childe looks through a historian's eyes, but he is far too sensitive to contemporary influence to ignore the new opportunities that were ready to his hand. Hence in this book he undertakes the difficult task of running the two methods, the historical and the sociological, in double harness. The plan of the whole book is historical: after a quick sketch of the first emergence of human societies in Palæolithic times, he follows their evolution in Britain down to the Roman period, with all the tale of invasions and cultural influences and the full archæological panoply of pot- and tool-typology. By dividing the space of time covered by the Neolithic, Bronze and Iron ages into nine parts, he even provides the first modern period-scheme for Great Britain comparable with the classic chronologies of Montelius, Müller and others on the Continent. Yet, throughout, social and economic changes are kept well to the fore, so that the book can with justice claim to be the first "to present a comprehensive account of the development of the societies inhabiting the British Isles in prehistoric times", and it is this aspect which is most stimulating and original.

The adoption of a "neolithic" economy, with agriculture and stock-breeding in place of hunting and food-gathering, must always cause an increase in population, and this fact, together with the soil exhaustion due to primitive agricultural methods, necessitates continual expansion on to new land. It was largely by this means that neolithic culture spread slowly westward from its eastern cradle until at last it reached our shores. Once arrived, this same economic urge dispersed it rapidly over the lighter soils of Britain, wherever simple hoe agriculture could be practised and flocks find open grazing. Prof. Childe makes the interesting point that one among the several distinguishable groups of neolithic settlers, the bearers of the Boyne culture, represent a rather different economy, the line of their settlement being dictated more by considerations of trade in gold and other metals than by those of husbandry. Although neolithic communities were very largely self-sufficing, there was one specialized industry of some importance—the mining of flint and extensive trading of axes made from it—which must have been in professional hands.

Side by side with the full neolithic societies there persisted a rather more primitive native culture which, although it had adopted certain neolithic traits such as potting, was still mainly dependent on the old food-gathering methods, and this element was to re-emerge in the Bronze Age, when for a time the relative importance of agriculture declined.

At the beginning of the Early Bronze Age the invasions of the Beaker Folk introduced a new ruling caste to dominate the old neolithic stocks. These newcomers, who seem to have been pastoral nomads, were able to extend over Britain "a degree of cultural uniformity . . . not repeated until Roman times". Although it would be folly to visualize a "Beaker state", their great holy centres of Stonehenge and Avebury, together with a widespread trade in luxury articles, show a considerable degree of co-operative purpose in both religious and commercial affairs. These Beaker pastoralists could spend the wealth they acquired as exploiting overlords on an improved material equipment; in particular, they provided important markets for the bronze and gold of Ireland, where a precocious knowledge of metallurgy and commerce was due to the tradition of the Boyne culture.

This same knowledge was inherited and developed in the Middle Bronze Age by the people of the so-called Food Vessel culture that grew up in Ireland and in Britain north of the Thames. Apart from their trade, the Food Vessel folk subsisted largely by pastoralism and hunting, and there is no doubt that they represent a reassertion of the old native tradition that we have seen persisting in Neolithic times.

In Wessex a wealthy aristocracy was in power in the Middle Bronze Age whose trade connexions were surprisingly far flung, extending to the Baltic, Central Europe and the Mediterranean. This Wessex society, with its hold upon the best land in the country, was so successful that numbers quickly increased under its rule, and the common folk, distinguished by their cinerary urns, expanded and spread far over England and Scotland and thence to Ireland.

Very important changes took place in the Late Bronze Age. In the first place, there grew up a caste of "international armament manufacturers" in bronze, perhaps detribalized, but wealthy and influential, who may have travelled the land in "veritable caravans", manufacturing and selling their wares. Prof. Childe is at his most interesting when he describes how this caste was ruined by the loss of markets after the introduction of iron.

Another still more significant change that took place later in this period was the introduction of plough tillage with settled fields and steadings, initiating the mixed farming that is still a force to-day.

Agriculture became increasingly intensive when the first iron-using immigrants arrived, and with this went a more developed social organization with nucleated villages as well as isolated farms. A new departure, prompted by the political and military conditions of the times, were the hill-top forts that might be either temporary refuges or tribal centres representing some degree of political unity among the farms and villages of their area.

With the coming of the La Tène Celts in the third–first centuries B.C., a fresh aristocratic class was instituted, particularly in the north of England, where a few ruling warrior families must have been the first patrons of the brilliant artists and skilled craftsmen who created the great British school of Celtic art.

Meanwhile, another group of La Tène Celts had established themselves in the south-west, originally to exploit Cornish tin, but soon spreading farther east and trading in lead, copper and iron as well as tin, and employing for the first time that most important social instrument, a standard currency.

So at last we reach the Belgic invasions of the first century B.C. that come already within the realm of written history. These part-Germanic part-Celtic people whose immigration into Britain is recorded by Cæsar, brought about far-reaching social change. They were ruled by princely dynasties, who established extensive kingdoms with capital cities that were political and commercial centres of importance. At the same time the Belgæ began at last the de-afforestation of the richer soils of England, and the tilling of the good land thus won with the heavy wheeled plough, so introducing the type of agriculture that was to be further advanced by the Anglo-Saxons and to last throughout our Middle Ages. This was the civilization which Claudius found established when he arrived with his elephants to conquer Britain for the Roman Empire.

In thus tracing social development in Britain from neolithic to Belgic times, Prof. Childe has accomplished something new and valuable. He has added solidity and human meaning to the old historical framework, while at the same time keeping the historical depth of perspective. If it is sometimes rather laborious to disentangle this social theme from the mass of archæological fact and description, that is because the author has too much respect for his reader to want him to accept his reconstructions without the evidence upon which they are based. Specialists will notice here and there inconsistencies and errors which can be attributed to the difficulties and haste imposed by war, but they do little to detract from the worth of the book as a whole. Indeed, after reading it, archæologists may well feel proud to recognize how far their work has gone towards recapturing the once-forgotten past of Britain so completely that the old distinction between pre-history and history is becoming more than ever meaningless.

J. J. HAWKES.

A SCHOOL CHEMISTRY

An Introduction to Chemistry

By A. C. Cavell. (1) Part 1 : Inorganic Chemistry. Pp. xiii + 512 + xiii. 6*s*. (2) Parts 2 and 3 : Physical and Organic Chemistry. Pp. xi + 513–712. 4*s*. (London : Macmillan and Co., Ltd., 1940.)

(1) A SPECIAL feature which is claimed for this book is the considerable care which has been taken to separate what the author considers to be necessary for School Certificate examinations and for examinations intermediate between this and Higher School Certificate, the latter material being given, along with historical notes, at the ends of the chapters. This separation does not seem altogether justified. The additional material on Avogadro's hypothesis (which is called Avogadro's law), for example (Chapter ix), would usually be found helpful by elementary students. The course provided, apart from the additions, gives the impression of a minimum one. Practical work and questions from various examinations are given ; in the questions the London General School Certificate examination is very sparsely represented.

The book opens with a historical introduction which is evidently based on good sources, except that Jabir and Geber are confused, as in other places (pp. 257, 310, 344, etc.). The definition of an 'element' on p. 10 is not very satisfactory, since the meaning of 'split', as applied to a substance, is not explained, and the definition of a 'pure substance', as given, would include solutions ; it would be more satisfactory to give the material on pp. 11–12 first. The atomic theory is briefly explained before the laws of combination, which is the historical order. It would have been possible, however, to re-word the definitions of atoms on p. 39 so as to take account of the existence of isotopes (which need not be mentioned) ; as it is, statement (ii), that "the atoms of a given element are identical", is not correct in the 'modern form' of the theory, which the summary claims to give. The author uses 'equivalent weight' for what is now usually called (following Faraday) the 'equivalent', and 'vapour density' is applied to permanent gases.

The theoretical sections are generally clear and adequate, and the order of the chapters is good. The non-metallic elements are dealt with first and the metals follow, after a chapter on electrochemical characters, which are made the basis of classification. This is satisfactory in an elementary course, although it places the metals in a very peculiar order from the point of view of the periodic law. Brief accounts of industrial processes are given. There is a chapter on volumetric analysis at the end, in which the definition of 'normal solution' given on p. 482 is incomplete, and does not agree with that on p. 491.

The style is generally good, but it is surprising to find on p. 482 the direction to 'tip' a solid into a vessel. Revision notes at the end of the book will be useful for reference. There are tables of logarithms and antilogarithms.

A few errors, some of which are common in textbooks, were noticed. It is scarcely correct to say (p. 144) that hydrogen is 'rather inert', since it combines directly with most of the non-metallic elements and with many metals, and reacts with a large number of compounds. The statement that argon was first called 'aeron' (p.118) is new to the reviewer, but may be correct. The eudiometer of Fig. 23 is Ure's, not Volta's, and on p. 160 the name is 'Warltire', not 'Waltire'. The product of oxidation of graphite is graphitic acid, not mellitic acid (p. 190) ; on p. 202 'linseed *oil*' is meant ; and on p. 210 Black's date is 1755, not 1775. On p. 222 the important fact that coal gas owes its poisonous nature to carbon monoxide (which is not stated on p. 227), should be mentioned. Carbon dioxide is usually said to liberate chlorine, not hypochlorous acid, from bleaching powder (p. 255), and since copper evolves hydrogen from hot concentrated hydrobromic and hydriodic acids, the basis of the argument on p. 305 is unsound. Bones are 'burnt', not 'distilled', to make bone-ash (p. 357) ; phosphorus was discovered by Brand, not Brandt, probably in 1674, not 1669, and it was made known by 'Krafft', not 'Kraaft' (p. 361). On p. 387 'Dobereiner' should be 'Döbereiner', and on p. 440 'Wohler' should be 'Wöhler'. The common error that the converter lining is used to dephosphorize the iron in the basic Bessemer process appears on p. 420 ; pure ferrous hydroxide is white, not green (p. 425), and ignited ferric oxide is insoluble in dilute acids (p. 426). Chrome alum does not usually crystallize after twenty-four hours from a solution which has been *boiled* (p. 478).

(2) Parts II and III are claimed to provide an elementary introduction to physical and organic chemistry sufficient for the first year of specialization after School Certificate, and are intended to bridge the 'wide gap' which the author finds between existing books of Certificate and Higher Certificate standards. Practical work is included. The section on physical chemistry (pp. 513–597) is largely concerned with molecular weight

determinations of gases and in solutions, with a short chapter on reaction velocity and equilibrium, and one on atomic structure, radioactivity and valency. The account of equivalent conductivity on pp. 551–52 is too brief to be of much value, and the definition of reaction velocity on p. 570 is incomplete, as it applies only to irreversible reactions. The course in physical chemistry is thus very elementary, but it will probably be adequate for the purpose the author has in mind.

The section on organic chemistry (pp. 598–701) is straightforward, and deals with typical classes of compounds. The old formulæ for glucose and fructose are given on p. 675, and the phenomenon of resonance in benzene is treated on pp. 678–688 as though it were a case of dynamic isomerism, which is misleading.

The book should fulfil the purpose for which it is intended, and it will assist teachers especially in providing some good laboratory work.

A WRITER TURNS FARMER

The Story of a Norfolk Farm

By Henry Williamson. Pp. 403+11 plates. (London: Faber and Faber, Ltd., 1941.) 10*s*. 6*d*. net.

READERS of Henry Williamson's books have long known that some four or five years ago he bought a derelict farm in Norfolk in a district thinly veiled under the pseudonym Whelk-on-Sea, and that he had settled down there with the view of putting it in good order and farming it properly. Few tasks could be more agreeable to a man of adventurous disposition: it involves serious difficulties, both material and human, and considerable financial risks, while failure, if it comes, is regarded as somewhat ignoble or at least in accordance with the forecast of local experts who "told you so". But success has a peculiar satisfaction, and for this men have been prepared to stake a good deal.

All this, and much more, is set out vividly by Mr. Williamson. From the outset he was under no illusions as to the magnitude of the task he had undertaken. In a preliminary look round he learned the local view of the farm; he was warned that this was no time to start farming, least of all for a beginner; he had no knowledge whatsoever of farming, and he took as his chief assistant a relative equally lacking knowledge and experience; and moreover he seems to have felt that he was regarded as lawful plunder by the supposedly simple country folk around. Right from the start he met with a full measure of troubles and difficulties. But he had several qualities to set against all this: a fixed resolve to carry the job through; the energy and enterprise to work himself and not simply to supervise others; he soon learned to manage his tractor, and he had a flair for hitting on the right course of action. Finally, he had the good sense to consult the county agricultural organizer, and fortunately for him Norfolk is particularly well served in this respect.

Of course, it all cost more than he expected, but reclaiming a derelict farm always does, just like restoring an old house. He had also some rather costly experiences with the old tenant and with an old cottager who refused to go. But he was fortunate in being able to continue his writing and broadcasting, and so kept the place going during the lean years.

Much of the book is autobiographical. "In telling the story of the farm," he writes, "I realized that it would be necessary to tell also part of the story of the farmer". These chapters will be particularly appreciated by those who already know and have enjoyed the author's earlier writings. Here he is engagingly candid: "With the exception of the salmon book, which was first class, the last three or four books I had published, while as good as most country stuff, were not much good, although in time students would find delight in finding out about the author, from the pages".

Later he tells of a "weekly nature article" written in an A B C tea shop, and if this is the usual practice of writers of "country stuff" it explains a good deal.

He gives sufficient technical detail for the agriculturist without tiring the general reader. He has much to say about the barley crop of 1938, one of the best in our time, on which, in common with many other farmers, he had counted hopefully; but unfortunately the price was nearly the worst in recent years so that he like many other farmers suffered severely through Nature's bounty.

In 1938 Mr. Williamson lost considerably. But in 1939 prices were better and his accounts balanced; from now on he should have some return until the next slump comes. The farm, however, was always much more to him than a mere money-making concern. He had the courage to refuse an offer of £600 a year for three years for the exploitation of a chalk pit, because this would have spoiled a beautiful part of England.

The book will be read with interest by all who think they would like a farmer's life, for it shows clearly some of the trials the beginner may encounter, and the satisfaction in overcoming them.

E. J. RUSSELL.

THE TORTUGAS LABORATORY

By Prof. K. M. Yonge,
University of Bristol

NEWS has recently been received that the Marine Biological Laboratory of the Carnegie Institution of Washington at the Tortugas Keys, Florida, has been closed owing to necessary restrictions of the Institution's programme in certain directions. The Laboratory buildings have been handed over to the United States Government, that portion of Loggerhead Key on which they stand having been originally leased from the Government for purposes of marine biological research.

The passing of this Laboratory, for thirty-six years one of the few centres of biological research in tropical waters, demands some words of farewell. Its origin is intimately connected with the history of zoology in the United States. Louis Agassiz visited the Tortugas Keys in 1851 in the course of his survey of the Florida reefs, and Alexander Agassiz spent some weeks upon them in 1881. His admirably illustrated report was published two years later in the *Memoirs of the American Academy of Arts and Science*. There is reproduced in "The Letters and Recollections of Alexander Agassiz" by G. R. Agassiz, a letter to Charles Darwin, headed Tortugas, April 16, 1881, in which Agassiz writes of his activities in mapping out the distribution of the corals.

Recollections of this visit must have been uppermost in his mind when Agassiz, in his capacity as a trustee of the recently founded Carnegie Institution of Washington, pressed for the addition of a Department of Marine Biology to its many activities. But he did more than suggest the site for the Laboratory: he provided, in the person of one of his former scientific assistants, Dr. A. G. Mayor, a director who was to control its activities with outstanding success from its inception in 1904 until his untimely death of 1922. It is impossible to think of the Tortugas Laboratory apart from Mayor. His greatest work was done at the Laboratory or on the numerous marine expeditions to the Bahamas and other islands of the West Indies, to Murray Island, Fiji and Samoa, financed by the Department of Marine Biology. His fundamental contributions to the study of Cœlenterates and Ctenophores were largely carried out at the Tortugas.

The wooden laboratory and living rooms were erected near the western extremity of the long sandy island of Loggerhead Key in the summer of 1904. A photograph reproduced in the third Year Book of the Carnegie Institution shows them as they were originally erected, on the bare sand fully exposed to the glaring sun. Visitors in later years were impressed with the wealth of vegetation which surrounded and shaded the buildings. But the coco-nut palms and ironwood trees were planted by Mayor to provide shade and some protection from hurricanes which may sweep with devastating force over this portion of the Gulf of Mexico during the autumn. With the passage of years additional buildings were added, while the capacious M.V. *Anton Dohrn* replaced the auxiliary ketch *Physalia*.

The reefs of the Tortugas form a rough circle, there being the usual sharp descent into deep water on the north-eastern, that is, weather, side. Here the force of the sea driven by the trade winds is too great to permit the formation of a sand key, but shingle ramparts of coral fragments have formed on the inner side of the reef, and in the shelter of these a few mangrove trees find precarious existence. Loggerhead Key lies on the south-west, in the lee of the reef complex, and its shores are buttressed by beach limestone. Other sand keys are scattered about, notably Long Key, which is relatively densely vegetated and provides a nesting place in the summer for hosts of sooty terns and noddies, as well as for the majestic frigate birds which batten on these smaller birds. The entire reef complex was, to me, vividly reminiscent of conditions on the reefs of the Great Barrier of Australia, which are moulded by the action of the south-east trades.

A unique feature is provided by the Marquesas Keys, which lie between the Tortugas and Key West and form an almost perfect ring. They contain no living coral but are formed of calcareous material of mixed origin thrown up above the surface and moulded by the action of the prevailing winds and currents.

The most remarkable feature of the Tortugas Keys is undoubtedly the immense brick erection of Fort Jefferson, which entirely covers one of the sand keys. Successive parties of visiting zoologists used to calculate the millions of bricks which had gone to its construction and the extent of the labour involved in their transport from Key West, seventy miles away. The military value of the Fort appeared problematical, but of its biological value there was, surprisingly, no question. On the piles of the wharf, in the deep shade cast by the crumbling planking overhead, grew corals

MEMORIAL TO DR. A. G. MAYOR AT LOGGERHEAD KEY, TORTUGAS. THE LABORATORY HUT IS SEEN BEHIND.

otherwise obtainable only in relatively deep water. Within the still waters of the wide moat there flourished, within easy access in all weathers, a representative collection of shallow-water corals and other organisms such as *Cassiopea xamachana*, on which much of Mayor's experimental work on Scyphozoa was conducted. During the great hurricane of 1919 the moat, which had stood undamaged for some seventy years, was breached on the north-western side, and further damage was suffered later. The result was to interrupt the previous flow of water through the moat so that those portions which remained filled constituted a sediment trap. A large-scale experiment in Nature was thus provided. A full list of the corals originally present had been provided by Vaughan in 1918 and they included all species typical of the inner reef flat. But when I examined the moat in 1934, apart from a few stunted specimens of other corals, the only common species was *Siderastrea radians*, which exhibited exceptional powers of modification, permitting life both in the surf region and also in still, sediment-laden waters.

It is natural first to consider corals in an account of the work of the Tortugas Laboratory. It was with these organisms and with the reefs which they form that Mayor and his principal associates, T. Wayland Vaughan, L. R. Cary and F. A. Potts among others, were primarily concerned. But the yearly visitors to the Laboratory covered a wide field in marine biology, as will quickly be revealed by reference to the contents of the well-known *Papers from the Tortugas Laboratory*, the thirty-second volume of which is now in course of publication. Mention of the work of W. B. Setchell on marine algæ, of A. L. Treadwell on annelids, of W. H. Longley on fishes, of D. H. Tennant and H. Lyman Clark on echinoderms and of P. Bartsch on molluscs, must suffice to indicate the range and value of this work.

After the death of Mayor in 1922 the Carnegie Institution did not appoint a new director, but Dr. W. H. Longley, of Goucher College, Baltimore, acted as executive officer in charge until his death in 1937, after which Dr. D. H. Tennant, of Bryn Mawr College, continued in the same capacity.

The Carnegie Institution has been most generous in its hospitality and many British workers have enjoyed the unique facilities of the Tortugas Laboratory. It was an exclusively male community, so that activities were never curtailed by any respect for the conventions of dress. One of the larger huts constituted a dormitory which contained a line of hammocks draped with mosquito netting. In the same hut were lodged the library and a laboratory, but a second, more recent, hut contained the principal laboratory and a working aquarium. Two motor-boats kept workers supplied with material, while the *Anton Dohrn* made occasional visits farther afield, as well as regular runs to Key West for stores and mail. The ingenuity and skill of Captain John Mills, engineer and seaman of unfailing energy and high spirits,

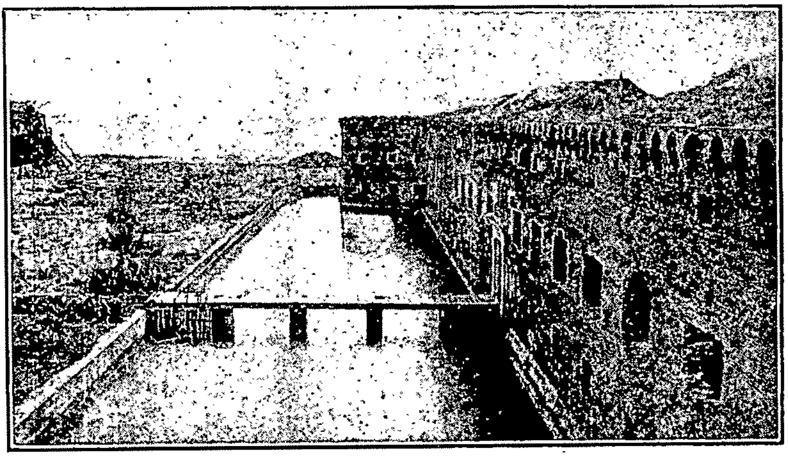

Fig. 2.

FORT JEFFERSON, TORTUGAS, SHOWING A PORTION OF THE MOAT AND THE BRIDGE LEADING TO THE MAIN ENTRANCE.

never failed to provide an answer to all problems of material and experimental equipment.

But for the War of 1914–18 it is possible that the Laboratory might, as Mayor wished, have been transferred to Montago Bay, Jamaica. Direct co-operation would thus have been possible between marine biologists from the United States and Great Britain. One can but hope that this aspect of the manifold activities of the Carnegie Institution of Washington may be resumed in due course, perhaps in collaboration with the Bermuda Biological Station.

CORROSION OF IRON AND STEEL IN SEA WATER*

THE eighteenth report of the Committee of the Institution of Civil Engineers on the Deterioration of Structures of Timber, Metal and Concrete exposed to the Action of Sea Water contains the final results of the fifteen years exposure of iron and steel specimens in the four harbours named, and also summarizes the results, previously published, of the five- and ten-year series. The observations on ferrous specimens are therefore now complete. Although the total number of bars exposed was large, only three of each material were exposed in each position, one of the three being removed at the end of each five-year period, so that there were no actual duplicates. It follows that accidental differences have a rather large effect, and it is only possible to make roughly quantitative comparisons, best expressed in graphical form. Naturally, wide differences were found between the results at different stations, partly on account of the prevailing temperature, but also owing to local circumstances. Thus, at Colombo the rise and fall of the tide is small, so that the half-tide specimens, being for most of their time in contact with water, were more nearly comparable with completely immersed specimens at other stations, and the bars exposed to the air were so often wetted by spray as to be comparable with half-tide specimens elsewhere.

All bars in this series of experiments were unpainted, but several materials were tested in two conditions: with adherent rolling scale and after removal of scale. The scale affords only temporary protection, and when flaking begins deep pits may be formed; so that although a scale-bearing bar may show a smaller loss of weight than its companion with the scale removed, it may actually be in a worse condition. Complications also arise from the accumulation of marine growths. In some instances this has led to a falling off of the rate of corrosion in the last five years of the test, the adherent growth being protective. On the other hand, considerable pitting may be found under the marine organisms.

Considering the materials in detail, cast iron behaved well in air, but when submerged was very liable to 'graphitization', the outer form being retained but the interior being converted into a spongy mass without strength. High-alloy steels of the austenitic type showed, as might be expected, a much higher resistance than carbon or low-alloy steels, but the cutlery type of stainless steel was less satisfactory when immersed in sea water. Such materials, from their high cost, can only be used in exceptional circumstances. Of the low alloy steels, those containing copper behaved well when exposed to air, but less well in sea water.

For practical purposes, mild steel and wrought iron are the most important ferrous materials, and it is this section of the report which will receive most attention. Using a system of averaging the results which was adopted after consideration, the numbers being too small for statistical treatment, it appears that under aerial conditions mild steel is less corroded than wrought iron of high quality; in fresh water there is little difference; and in sea water the wrought iron has the advantage. Some remarks on the effect of impurities in steel call for comment. The steel with high sulphur was also high in phosphorus, and the discussion seems to imply that the influence of these two elements would be in the same direction, which is unlikely. There were no specimens in which sulphur and phosphorus were varied independently.

On the whole, the results of these extensive field tests, carried out over a long period and with careful planning, are very much what might have been expected. The work of the Committee has, of course, covered much more ground than that of the present report, as it included both timber and concrete structures, as to the resistance of which to marine conditions there was much less information available. Of iron and steel it may be said that the inherent resistance of the ordinary varieties to marine corrosion does not vary very widely and that some form of protection is nearly always essential. Much more work on the nature of the corrosive process is needed, and is now actively in progress.

THE BANANA IN CENTRAL AMERICA

II. THE CONTROL OF CERCOSPORA LEAF DISEASE

BY PROF. C. W. WARDLAW,
UNIVERSITY OF MANCHESTER

THE leaf spot disease of bananas caused by *Cercospora musæ*, Zimm., though widely distributed in the Indo-Malayan and Australian regions, was not recorded in the western tropics until 1934. During the brief period of two or three years from its first recognition in Trinidad[1], it had appeared with epidemic intensity in many of the Caribbean islands and on the mainland of Central and South America, and by its destructive effect on plantations showed itself to be a disease of first-class economic importance. In the Republic of Honduras, where successful control measures were eventually worked out, as described below, the disease was first definitely recognized towards the end of 1935, at which time the intensity of infections suggested a development period of perhaps twelve to eighteen months. The data available, unfortunately, throw little light on the question as to how this malady was introduced into the Caribbean or whether its spread took place from one or several centres of infection.

Briefly, the disease manifests itself as a profuse spotting of leaves ; the tissue around the spots begins to die rapidly, and large, coalescing dead patches appear, so that in severe infections the leaf may be more or less completely destroyed. Bunches borne on affected plants show slow or arrested growth, behave abnormally during development and subsequent ripening, and commercially are valueless[2].

The success eventually achieved in Central America in controlling leaf disease is to be viewed in relation to previous work undertaken in Australia. The literature up to 1935 shows that no control measures had, in fact, been worked out[3]. In particular, dusting and spraying with fungicides had not met with the desired measure of success. Removal of infected leaves, fungicidal treatment of suckers, different spacings of plants and the growth of cover crops, all yielded results which were either negative or uneconomic.

When Cercospora leaf disease became established in the vast banana plantations in Central America, the economic losses, within a very short time, were formidable, and it was evident that some measure of control *must* be secured if a major agricultural disaster was to be avoided. Only those who have ridden for hours through miles of scorched, brown plantations, with extensive defoliation in progress, and everywhere small worthless bunches ripening on the plant, and who, by contrast, have seen the leafy greenery of a first-class plantation in full production, can appreciate the havoc wrought by this new malady as it waxed to epidemic proportions.

Here indeed was a challenge. The scientific staff of the principal fruit company spared neither labour nor expense in an effort to determine whether or not thorough dusting or spraying, repeated as each new leaf appeared, would give protection against the disease. For it should be noted that a monocotyledonous plant such as the banana, which produces its complement of some twelve to fifteen large leaves one by one at intervals of two to three weeks, according to growth conditions, presents a problem of unusual difficulty when it is a question of securing adequate spray coverage on a majority of the leaves. The work of Stahel[4] on *Cercospora musæ* as it affects the Congo banana in Surinam had shown that only the young leaves in the centre of the foliage crown were susceptible, and hence, for thorough protection, each new leaf should be sprayed as it emerges from the top of the pseudostem and begins to unroll. Actually, more recent investigations have shown that the older leaves of the Gros Michel are also susceptible ; but this only adds to an already exacting task and justifies the present procedure in Central America of spraying plants right through to the harvesting of the bunch. The problem confronting banana growers, then, was twofold, namely, the application of dust or spray fungicide over vast acreages, and the frequent treatment of plants of all ages throughout the year. Truly a formidable task and one, moreover, to which it seemed improbable that there could be an economic solution.

As the programme of experimental work was steadily pursued, the epidemic took an ever-increasing toll of plantations, and it was evident that the industry was faced with the most serious crisis of its history. Or, as one writer, with characteristic Latin-American emphasis, put it : "Leaf disease has made a dwarf of Panama disease". At length it began to be apparent, though final confirmation was far from having been obtained, that by spraying plants in short cycles of two to three weeks, that is, as new leaves emerged, with Bordeaux Mixture and other copper-containing preparations, a considerable measure of protection against leaf spotting was achieved. At this point the whole situation had become so critical that it seemed desirable that action should be taken on the preliminary results obtained, and the courageous decision was reached to install stationary spraying apparatus on a gigantic scale, the equipment to include power-houses, large spray-mixing tanks, pumping units and the materials for an ample pipe-line system extending right through the plantations. It was eventually found that a block of seven to eight hundred acres made a satisfactory unit for a single spraying 'project', several such units being necessary on each large banana division. On the Ullua River (Republic of Honduras) there is to-day a continuous area of 36,000 acres (about 60 square miles) under permanent pipe-line spray control. Altogether, in Central America, more than 100,000 acres are now equipped with stationary installations. Once again, the industry is in a state of high productiveness, and notwithstanding the heavy expenditure on spraying equipment and on the machinery for overhead irrigation, good profits are being made. The control of leaf disease probably represents one of the greatest achievements in the history of phytopathology.

Fig. 4.

BANANA PLANTATION IMMEDIATELY AFTER DUSTING BY AEROPLANE.

Before proceeding to an account of the equipment and its manipulation, reference may be made to the subject of fungicides. Many have now been tried and in various degrees have been found to possess practical value. By all tests and criteria, however, experience in Central America has consistently pointed to Bordeaux Mixture as the most satisfactory fungicide for the control of leaf disease.

Reference may also be made to dusting by aeroplane. Briefly, spray has proved superior to dust: the latter is quite expensive and does not give the same certainty of control as spraying does. In practice, dusting by aeroplane is rather a tricky business, and, moreover, the period each day when applications can usefully be made is very brief; that is, in the early morning while dew still remains on the leaves. Dusting by aeroplane probably has its place, however, in those areas where the extent and duration of productiveness

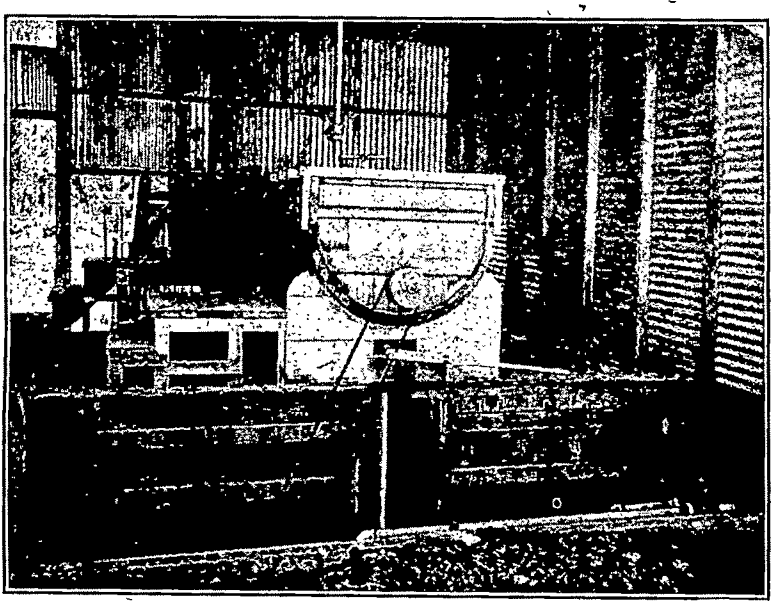

Fig. 5.

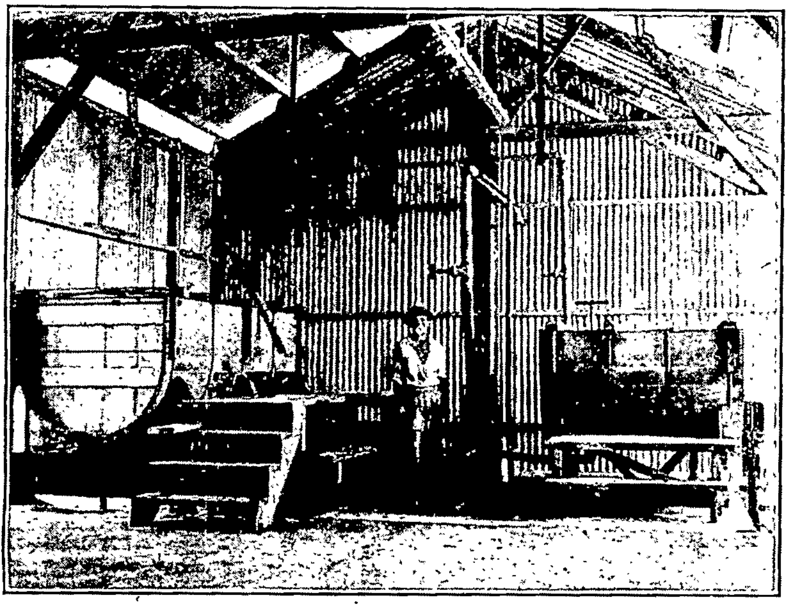

Fig. 6.

INSIDE THE MIXING SHED. THE OPERATOR IS STANDING ON THE PLATFORM ABOVE THE LARGE MIXING TANKS ; RIGHT, THE LIME DEGRITTER ; LEFT, THE COPPER SULPHATE SOAKING TANK.

do not warrant the installation of permanent, stationary equipment.

It should also be mentioned that the methods of cultivation used in plantations in Central America largely, if not entirely, preclude the operation of mobile spraying units, since the plantation floor is strewn with decaying stumps and logs, is rough and irregular in the absence of mechanical tillage, is overgrown with vines and shrubby vegetation, and is dissected by deep drainage ditches and in some instances by irrigation canals.

The spraying equipment, which now constitutes such a characteristic feature of banana plantations, has been derived, with modifications dictated by experience, from that used in United States orchards. Driving power for the pumps and mixing tanks is provided by a 40–50 h.p. Diesel engine. A spray pump, of the three-cylinder vertical type, with a capacity of 60 gall. min., at 600 lb. pressure and a speed of 120 r.p.m., has been found adequate for an 800-acre block operating on a 14-day spraying cycle. It may be noted that the high pressure under which the spraying fluid is maintained is of the greatest importance in providing a good coverage. Side by side with the power house is the mixing house where the spray is prepared. Bordeaux Mixture having come into general use as the most effective fungicide, the equipment of the mixing house has been specially designed to make its preparation as simple and efficient as possible. The two main mixing tanks, each of 2,000 gallons capacity, are provided with four propeller agitators with a central bearing. The warehouse floor, tank tops, and the floor of the railway car (in which materials are delivered) are all on the same level, thus facilitating the handling of materials and economizing labour. Situated above the two large tanks is a smaller tank described as a lime degritter (Fig. 5). Of approximately 300 gallons capacity, it is provided with an agitator which can easily be started and stopped. In this tank the proper quantity of lime is mixed with 250 gallons of water and vigorously agitated for as long as possible. Then, before use, during a period of five or more minutes, the grit is allowed to settle and the milk of lime drawn off through a 2-in. pipe which projects some three inches above the bottom of the tank. The copper sulphate solution is prepared in another tank which is divided into four compartments each of 200 gallons capacity (Fig. 6). Each compartment is fitted with a tray which holds the bluestone and

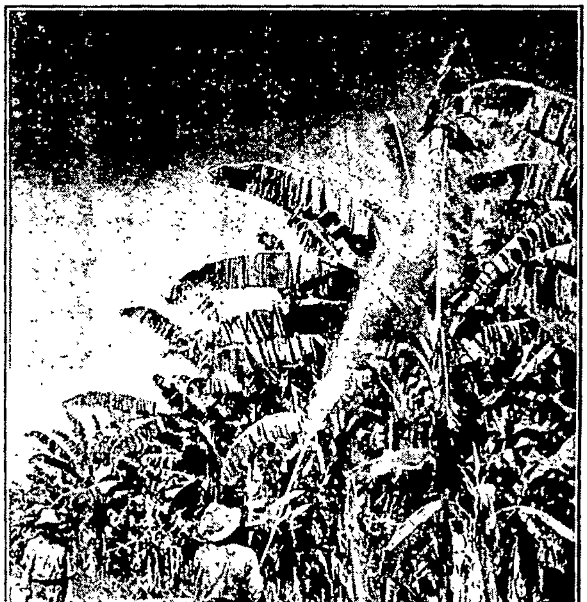

Fig. 7.

SPRAYING PLANTS OF MEDIUM STATURE.

descends some four inches into the water. For 2,000 gallons of spray of standard strength (that is, 5-5-50), 200 lb. of copper sulphate would be placed in one of the trays ; at tropical temperatures this quantity will dissolve in about two hours. Mixing can be continued indefinitely by using the soaking tanks in rotation. The charge of copper sulphate solution is led into the large mixing tank through a 1·25-in. brass pipe, header and rubber hose. In Honduras, the method used in the preparation of Bordeaux Mixture is to add dilute copper sulphate solution to concentrated milk of lime. The latter is therefore run into the mixing tank, and the former, diluted to the required extent in a swirl box by the addition of water from a 3-in. hose, is added.

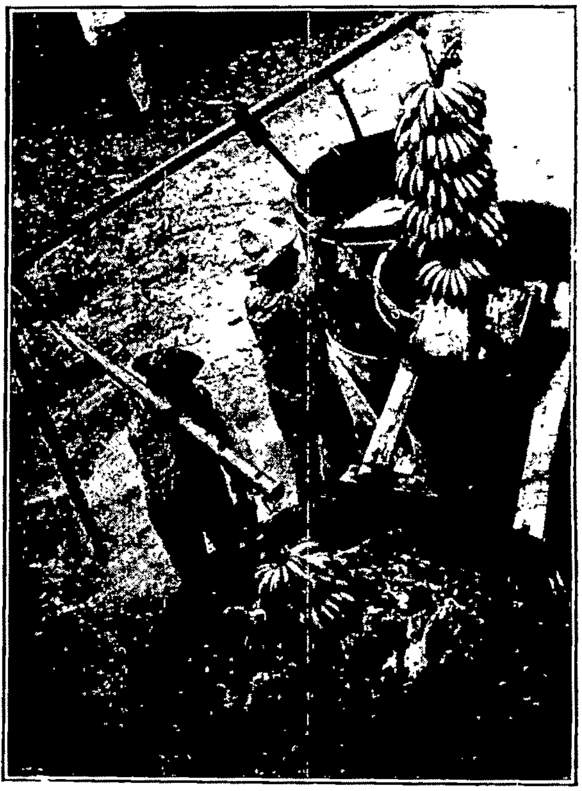

Fig. 9.

Removal of spray residue. The nearer bunch is being dipped in the acid bath ; the further bunch is being drained before going into the water baths.

The pipe system used for the distribution of Bordeaux Mixture from pump house to plantation consists of 2-in. mains, 1·25-in. laterals, and 0·75-in. sub-laterals, all suitably galvanized. An economic and effective layout of pipes is designed separately for each project. As an indication of the scale of a typical unit it may be mentioned that main lines may extend to 10,000 ft., laterals to 4,000 ft., and sub-laterals to 800–1,000 ft. The spacing between sub-laterals may range from 160 ft. to 240 ft., this being determined by local factors such as the position of open drains and the conditions of the plantation floor. The actual installation of these extensive pipe-line systems has been accomplished by quite inexperienced labour, recruited locally. The pipes are simply laid on the ground. As to the very considerable detail relevant to mechanical aspects, blockages, deterioration, etc., it need only be said that each and all are the subject of careful study, and that a special repair and maintenance squad is constantly at work, supervising, testing and where necessary effecting desirable changes. The actual distribution of spray is by means of hoses ; these are attached to the delivery pipes and dragged here and there over a limited area as required (Fig. 7). Eight to ten hoses may be in operation in one small area, and each spray gun may be opened and closed several times per minute. In these circumstances it is evident that very rapid changes in pressure may take place in the system : the undesirable effects which would normally result have, however, been satisfactorily overcome by the insertion at suitable intervals of vertical stand pipes (Fig. 8) ; these are 3 in. in diameter and 4 ft. high ; the air cushions which they provide reduce water hammer and effect a balancing of pressure at the delivery nozzles.

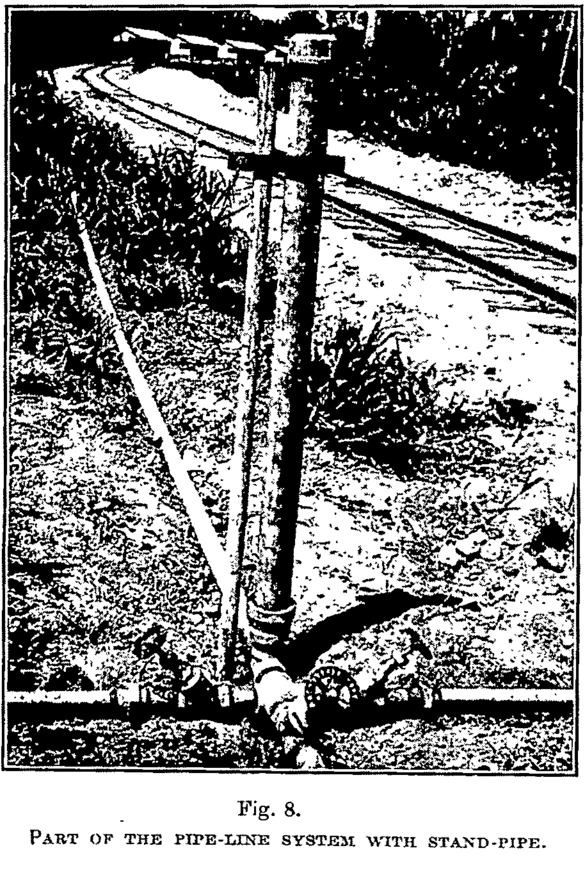

Fig. 8.

Part of the pipe-line system with stand-pipe.

Spraying operations are carried out by local labour. Members of the spray gang are always conspicuous by the whitish blue deposits of Bordeaux Mixture on their hats and shirts. They take a great pride in their work and describe themselves with all due solemnity as 'chemists'. The effective spraying of bananas is not an easy task: every stool includes plants of three ages (that is, the oldest plant bearing a more or less well-developed bunch, its immediate successor, also a tall plant, and a still younger follower); and there may be as many as 300–500 stools per acre. To lack of uniformity in the height of plants to be sprayed is added a further difficulty in that in plantations more than five or six years old the plants are very irregularly distributed. The leaf itself offers still further obstacles in that its waxy surfaces, vertically or steeply inclined when young, are not easily wetted. Nevertheless, all these difficulties have been overcome. Each stool is thoroughly sprayed from four positions, the jet being directed just below the top of the highest leaves (30–40 ft. above the ground), the lower leaves being adequately wetted by the downwardly drifting spray. Details of the construction of spray guns need not be entered on here; the essential point to be noted is that, at the high pressures used, the Bordeaux Mixture is applied as a veritable fog, the coverage afforded being surprisingly good and very effective. At the end of each day's work, the pipe-line system is washed out and left full of clean water.

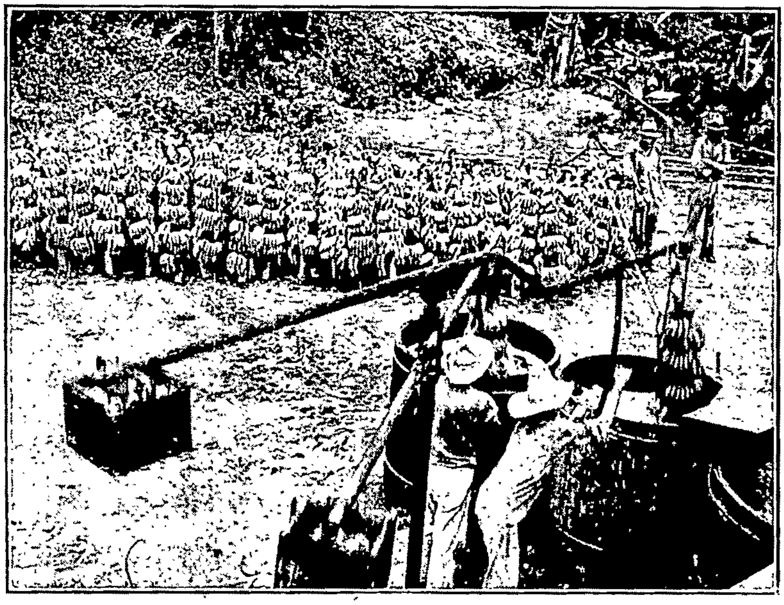

Fig. 10.

SCENE AT FRUIT DEPOT. THE COUNTERPOISE APPARATUS FOR DIPPING BUNCHES IS SEEN IN OPERATION.

The use of Bordeaux Mixture necessitates the removal of the spray residue from the fruit. This is effected by dipping freshly harvested bunches in a dilute acid bath followed by thorough washing in water—a procedure which removes the detritus accumulated during growth and therefore improves the appearance of the fruit (Figs. 9 and 10).

Installation, operation and maintenance have been the subject of careful costing. The control of leaf disease, involving as it does continuous spraying throughout the year at intervals of two to five weeks, is, of course, expensive. Nevertheless, experience has shown that the costs can be met and that considerable profits can be made. Most important of all, an epidemic disease which threatened a major industry with extinction has been conquered—an achievement which must be highly gratifying to those who have been associated with this notable phase of tropical agriculture.

The control of leaf disease has many aspects. A few of these may be briefly noted here. While leaf disease can be controlled by the application of copper-containing sprays, knowledge of meteorological conditions, rate of development of leaves, and of the seasonal intensification of the disease is necessary in order that control measures may be undertaken at minimum cost. In fully grown plantations, the control of severe leaf disease is difficult and costly, and, as a rule, requires a considerable period of time to achieve. Experience has shown that the best procedure is to cut down all plants in affected areas and to secure control as the young plants come up. Considerable difficulty has been experienced in obtaining control in young plantations situated in close proximity to severely affected areas; instances are known where control could not be obtained until the adjacent diseased plantations had been cut down. Since adult leaves as well as young ones are susceptible, it is considered advisable to spray the entire stool thoroughly on each occasion, continuing through to the harvesting of the bunch. Good spray coverage means good control; the best coverage is obtained when properly prepared spraying liquid is applied under high pressure. In regions where growth is rapid, control is sometimes difficult to obtain; a close spraying cycle is then necessary, and should only be widened when sufficient knowledge of the local behaviour of the disease has been obtained. Spraying makes for an increase in the bunch weight, but injury due to scale insects is intensified. Pruning of spotted leaves not only serves no useful purpose but even accentuates the effects of the disease. The fact that bad areas must in some instances be cut down before control in adjacent areas can be obtained is an indication of the important part played by the locally produced spore population.

Satisfactory as the position now is in respect of commercial control, it is generally admitted that costs are still too high, that many aspects of the disease, including the effect of soil and climate, are still imperfectly understood, and that research work on a comprehensive basis should be consistently pursued.

OBITUARIES

Prof. Vito Volterra, For.Mem.R.S.

VITO VOLTERRA, who died on October 11, 1940, was the best known of the many fine mathematicians whom Italy has produced in our time. He knew everybody and went everywhere. He was a member of every academy from Leningrad to Washington. One found him lecturing now at the Sorbonne, now at Princeton, now at Prague and now at Madrid. He was a great personage in Rome for many years, professor at the University, member of the Senate, president of the Lincei; he had his hospitable flat in the Via in Lucina near the Piazza Colonna, and his Villina Volterra at Ariccia on the Appian Way. But like many another Italian scholar, he failed now and then to see eye to eye with his Government; his family were more incautious than he, and troubles came to them and to him; but he worked on to the end.

Volterra was born in or near Pisa, in 1860, and became a professor at an early age in that little Tuscan university; later on he went to Turin, and thence to Rome. His first papers were physico-mathematical, on statical electricity, elasticity, optics. But when he was twenty-seven he wrote a long paper on linear differential equations, following it up by a second part five years later; and these two papers were the foundation of his career. They lasted so well that he republished both of them in 1938, fifty years after they first appeared, the one with little change the other with none at all, as the first fifteen chapters of his last book in Emile Borel's series, on "Opérations infinitésimales linéaires". Volterra was soon famous for his skill in differential equations, and for the ingenious uses he put them to. By the time he was fifty, the Royal Society made him a foreign member, the French Institute did the same, and other honours fell thick upon him. In 1913 he wrote his "Leçons sur les équations intégrales et les équations intégro-différentielles", for his friend Emile Borel; he had spoken on the same theme to the Cambridge Mathematical Congress of the year before. Many similar books followed, some in Borel's series, some published elsewhere, and all are still in use. The last of them, published with M. B. Hostinsky's help less than three years ago, is the one which harks straight back to his youthful essay of 1887.

That differential equations have become vastly important to physical science is not all Volterra's doing, but he has done a lion's share. He used them in one of his early papers (in 1898) in the study of seiches, which Forel had been observing in the Lake of Geneva, which Chrystal was to study soon afterwards at Loch Earn, and which Proudman has since studied by methods similar to Volterra's. Even before this he had applied his equations to elastic torsion, magnetic hysteresis, and certain other phenomena which he liked to call "hereditary", because they involve the past history of the system. He lived to see his methods and his equations used in the most diverse fields, in connexion with matrices, in Smoluchowsky's study of the Brownian movement, in the theory of probabilities, even in economics and statistics.

Differential equations crop up of themselves in the study of natural selection. Volterra's daughter Luisa had married Dr. Umberto d'Ancona, then a young zoologist, now a leading authority on Mediterranean fish and fisheries; and Volterra was led to apply his mathematics to the struggle for existence among fish. The story begins with an imaginary sea inhabited by sharks and codfish, the devourers and the devoured: with the result (of which Herbert Spenser had caught more than a glimpse) that the two species increase and diminish by turns, in waves which never damp down to equilibrium. Volterra developed the subject in a great many papers. He brought it before the Oxford meeting of the British Association in 1926; he discussed it with the International Council for the Exploration of the Sea at Copenhagen in 1928; he gave lectures on it at the Institut Poincaré, and published them as "Leçons sur la théorie mathématique de la lutte pour la vie" in 1931. He revised and epitomized the whole matter at the Mathematical Congress in Paris in 1937; and here (if not before) he brought out the curious proposition—he called it a *paradoxe démographique*—Si l'on conserve sans altération les coefficients d'accroissements des espèces, une seule exceptée, la moyenne de la population de cette espèce ne changera pas, tandis que les moyennes des populations d'autres espèces changeront. An early abstract of this work of his had appeared in NATURE (I translated it for him) on October 16, 1926, p. 558.

Volterra went much farther in his later papers. He found in biological variation an analogue to Hamilton's principle in mechanics, with Maupertuis's principle of least action not far behind. He reduced the fluctuation equations to a Jacobian partial differential equation, and obtained the corresponding integrals. It is unlucky for us biologists that such paths go smoothly for a while, but then soar to heights unclimbable. Prof. Kostitzin's little book, "La biologie mathématique", for which Volterra wrote a preface, and which was reviewed at length in NATURE (of June 5, 1937, p. 943), is enough to show the range and the ultimate complexity of the biological problems. Volterra was not the first in this fertile field. He was forestalled, though he did not know it, by Ronald Ross's "Malaria Equations", by some of W. R. Thompson's studies of insect parasitism, and fully and precisely by A. J. Lotka in his "Physical Biology" (1925) and earlier papers. How much Volterra added of his own is not always easy to say, but he toiled over the subject, and enlarged and clarified it. D'ARCY W. THOMPSON.

VOLTERRA'S fundamental ideas have enriched many branches of mathematics. Most of these ideas can be traced back to his earliest papers, and originated in attempts to solve physical and mechanical problems. Though his books, and especially their titles, might suggest that he was primarily a pure mathematician, his thoughts never ceased to be active with problems of the actual world; he was not content with having devised elegant solutions of problems of applied mathematics, until the result had been tested by measurements on models or observations of the natural phenomena concerned. In his work on elasticity, for example, he made many clever experiments on rubber models, and his pupils or colleagues supplemented these experiments by others in which they used the double refraction method to measure internal strain. Again, in discussing heat flow in the earth, he applied his calculations to the St. Gothard tunnel, and pointed out the practical importance of the theory in tunnel boring. A paper he wrote on the Hall effect was followed by similar observations to test the influence of a magnetic field on the resistance of a metal plate.

Among his most important work was that on integral equations with variable limits, which originated in 1884 from a problem in electrostatics. He pointed out the analogy with limiting systems of algebraic equations, and in 1896 developed an elegant solution in terms of iterated kernels. Later he applied his methods to multiple integrals and partial differential equations.

So early as 1887 Volterra introduced the conceptions of 'functions of lines' (or rather curves) and functionals, and in later years developed a calculus of functionals that proved to be of great value in treating integro-differential equations, such as arose in his theory of 'hereditary' phenomena in physics and biology.

Volterra also showed how to apply Green's theorem in n dimensions to extend Riemann's method of characteristics so that it could be applied to solve boundary problems for linear hyperbolic partial differential equations in n independent variables. In particular, he discussed the cylindrical wave equation, and found the appropriate analogue of Kirchhoff's theorem on wave motion. The idea was also modified to suit systems of equations that occurred in his researches on wave motion in elastic media, and to parabolic equations. He constructed a theory of the differential and integral calculus of substitutions in connexion with the theory of ordinary linear differential equations, and showed that Fuchs's results could be interpreted as an extension of Cauchy's theory of residues. S. CHAPMAN.

Miss Bertha Porter

THE gifts of mind and character which, though they may fall short of brilliance, ensure that the holder, unless met by too adverse a fate, will presently find an opportunity for free development and fruitfulness, should be given high rank in a hierarchy of service. Amongst such souls Bertha Porter may be assigned a place.

Born at the end of the early Victorian period to the home of a successful architect in whose house in Russell Square many highly cultured men and women might be met, Bertha Porter early showed a keen interest in knowledge as such, and, after her short school-time at Bedford College was over, pursued this and that with diligence. This mental alertness, combined with methodical habits and self-discipline, soon made her serviceable, so that the student of psychical research was in her debt before she contributed to the building up of the "Dictionary of National Biography".

University College was so near Bertha Porter's home that the eager student was quick to catch the scent of a new trail there, and before long she was swept in, this time finally, to furnish the Egyptological *atelier* with a labour-saving appliance. Erman in Germany and Griffith in England, aware that for continuity of study the student of their day greatly needed a survey of past research, had perceived Miss Porter's qualifications for bibliographical work. A brief visit to the University of Göttingen had provided her at least with valuable contacts.

After five and twenty years of exact and patient research, Miss Porter had almost brought her labours to the point of publication when it became plain that further progress lay where she would no longer feel at ease. Other women were enlisted to aid her (1924), and gradually replaced her failing energy. But so solidly and accurately had the foundations been laid that the six volumes now published (out of eight or nine) are confessedly almost above criticism. "Porter and Moss" (or, to give the work its proper title, "Topographical Bibliography of Ancient Egyptian Hieroglyphic Texts, Reliefs, and Paintings") is now a household word in Egyptology.

Ten years in bed, after so many at the desk, were cheerfully met with the same patience and old-fashioned humour. Through life Miss Porter had kept to a quaint Victorian dress, as if in quiet assurance that that era needed no apology.

NEWS AND VIEWS

President Roosevelt and Aid to the Democracies

PRESIDENT'S ROOSEVELT's speech at the dinner of the White House correspondents in Washington on March 15 will rank in future ages among the most momentous events in world history. Thereby he laid down a pledge that the efforts of a great and united people should suffer no relaxation until the total victory of the democracies over the menace of the aggression and tyranny of the dictators has been won. In his review of the events of the preceding week, following on the passing into law of the Lease-and-Lend Bill, or as he now preferred to call it the Aid-for-Democracies Bill, he stressed with the utmost emphasis two elements. Of these the first was that of speed. "The urgency," he said, "is now . . . the time element is of supreme importance," and he went on to recall, what was by that time well known to his audience, how the Bill was signed by him within half an hour of being agreed upon in both Houses of Congress, and that five minutes later he had approved a mass of articles for immediate shipment, of which, he added, many were already on their way. The second element upon which he dwelt with if anything even stronger emphasis was the comprehensive nature of the help for which democracies—among whom he went on explicitly to include China—may look to the United States, whence will come munitions in any and every form, planes, guns, tanks, ammunition, food, and the ships to carry them.

With a generosity without parallel in history, the total resources of the United States are placed at the service of those who are engaged in the struggle on behalf of free institutions; and the United States now is, in the fullest sense of the phrase, the arsenal of the democracies. Mr. Roosevelt called upon every grade of the people of the United States for great sacrifices in the interests of those in the fighting line; but he made this demand upon the national will to sacrifice and to work with confidence. For, as he had already pointed out, the decision had been fully argued by every means of popular debate, and the decisions of democracy when made were proclaimed not with the voice of any one man, but as the voice of one hundred and thirty millions. For every one of these millions the President said, the "ultimate stakes" are what he had already marked on a previous occasion as the four freedoms—freedom of speech and expression, freedom to worship God in his own way, freedom from wrong and freedom from fear.

This Presidential speech repays careful study. It is close packed with virile and telling phases, which owe nothing to rhetorical ornament. They have strengthened the enthusiasm of the people of the United States, and enheartened everywhere those who are engaged in the life and death struggle for the continued existence of democracy. Yet even the urgent and vital necessities of the immediate conflict must not be allowed to obscure the supreme significance of the President's pledge that "when the dictatorships disintegrate, . . . then our country must continue to play its great part in the period of world reconstruction for the good of humanity". Mr. Churchill, in acknowledging with gratitude in in the House of Commons the passage into law of the Aid-for-Democracies Bill, spoke of it as a Magna Charta for free nations.

It would indeed be rash to attempt to forecast even in part the implications of the close co-operation which this far-reaching measure will demand for its fullest implementation; but that Mr. Churchill's analogy is no rhetorical compliment, but rather an inspired vision of its potential force, is endorsed by Mr. Roosevelt's recital of the creed to which it will be his endeavour that reconstruction shall conform. Thus it runs: that any nationality, no matter how small, has the inherent right to its own nationhood, . . . that the men and women of such nations . . . can through the processes of peace serve themselves and serve the world by protecting the common man's security, can improve the standards of healthful living and provide markets for manufacture and agriculture. Through that trend of peaceful service every nation can increase its own happiness, banish the terrors of war and abandon man's inhumanity to man". Such then is the ultimate goal to which the President looks as the justification for his own resolve and that of the people of the United States to implement to the fullest extent the Aid-for-Democracies Bill, and for which he trusts it may be said in the days to come that "our children and our children's children will rise up and call us blessed".

Science and Post-War Reconstruction

PRESIDENT ROOSEVELT's momentous pronouncement on "the great part" which the United States will play in post-war reconstruction will be received with heartfelt relief and gratitude by all who hold fast to faith in the future of democracy as an assurance of justice as between man and man and between nations in the new world order which is to come. Most of all, perhaps, is this clearly appreciated by men of science, to whom it is a fundamental conviction that the progress towards ideals of democracy —freedom of thought and action, justice and tolerance —is to be achieved only by the application of science and scientific modes of thought to the problems of securing the conditions in which alone free institutions can function freely.

This is not merely a matter of broad and far-reaching principles—principles framed, indeed, in the Christian spirit, but to which all, irrespective of creed, race or nation, will subscribe; but it involves as a practical measure the solution of a thousand and one subsidiary problems affecting the daily life of the individual and the group or nation in which he has his being, and vitally affecting the performance of his function as a free member of a free society—problems of personal and social hygiene, education, food supply and an innumerable host of others upon which scientific workers have long been engaged and which still engage their thought even amid the preoccupations of war. In the field of the relations of national groups President Roosevelt's Aid-for-Democracies Bill has already paved the way for the lines of future inquiry and research. The vast range of inquiry into the conditions of ultimate security for humanity will draw upon the resources of all sciences, and not upon the biological and social sciences only.

New President of the American Association

Dr. Irving Langmuir, who has been elected president of the American Association for the Advancement of Science, is a well-known figure in international science, and has interested himself particularly in borderline fields extending between physics and chemistry. Early work by Langmuir on the adsorption and reactions of gases at solid surfaces proved to be of fundamental importance to an understanding of many of the phenomena of colloid chemistry, heterogeneous catalysis, surface tension, and even of such an apparently unrelated subject as thermionic emission. One everyday consequence of this work was the gas-filled electric lamp. Arising out of these investigations came the conception of the orientated monolayer as the state of material at phase boundaries, a view which has led to important advances of our knowledge of the mechanism of lubrication of metal surfaces, and of the structure of oil films on liquid surfaces. In 1938 he visited Great Britain as the first American to deliver the Pilgrim Trust Lecture before the Royal Society when he gave a characteristically informative and fascinating account of his views on the structure of protein films (see Nature, December 17, 1938); and he also delivered the Faraday Lecture of the Chemical Society, when he dealt with monolayers on solids. Dr. Langmuir received the Nobel Prize for chemistry for 1932 and was elected a foreign member of the Royal Society in 1935.

Manchester Literary and Philosophical Society: Air Raid Damage

The Manchester Literary and Philosophical Society lost its historic home, library and Dalton and Joule memorials in an air raid through the spread of a fire from warehouses. In the eighteenth century, when those who could not subscribe to the articles of the Anglican Church were excluded from the universities, academies were founded in several places, that at Manchester being a specially important one. Among the intellectual leaders of the time were Dr. Thomas Percival, a medical pioneer, and Joseph Priestley; and one of the teachers employed by the academy was John Dalton. A group meeting at Dr. Percival's house founded the Literary and Philosophical Society in 1781, and it met shortly afterwards for a time in the room attached to the non-subscribing chapel in Cross Street, which has also been burnt out. A little later the Society acquired the fine Georgian house which it has now lost, and, in that house, Dalton did his scientific work. A great deal of his apparatus and many of his notes had been placed in the basement to diminish risks, but the fury of the fire destroyed nearly everything. Dalton's watch, Joule's chronometer, some of Dalton's notes and a few small pieces of apparatus have been found and salved.

The Society has also lost, at least for a time, an income it has long received from a trust established on its behalf. In spite of these misfortunes of war, it is maintaining its activities and is asking the cultural societies of Manchester to take part in a co-operative effort for a common home worthy of the long tradition of scientific leadership associated with the names of Dalton, Joule and many later workers belonging to what is believed to be the next oldest learned society in England after the Royal Society.

The Science Museum: Air Raid Damage

The Science Museum has suffered damage by bombs during air raids on London. A number of bombs have fallen in the vicinity of the Museum, and although the building has suffered from the loss of windows, little damage has resulted to the collections. In one attack practically all the windows on one side of the building were broken, as well as many of the roof lights. Fortunately, the damage sustained by the Museum collections is slight, although a number of exhibition cases in certain galleries have been damaged by blast. Although the Museum is closed to the public, the Science Library continues to remain open, and to afford the usual facilities to readers and borrowers.

The Respirator in an Emergency

The Prime Minister and the Lord Privy Seal have both recently referred to the possible use of poison gas by the enemy. Although expressly forbidden at the Geneva Convention signed by all the powers, there are indications that make it highly desirable that the people at large shall take heed of the possibility, and review their individual and personal protection against this most horrible form of attack. Everybody has been provided by the State with an efficient gas mask or respirator; it is a simple matter to see that it is in good order and is instantly available at all times. It is not enough, however, to carry the respirator; the owner should practise frequently taking it out of the case and putting it on, holding his breath in the meantime so that the operation becomes a matter of routine which can be done in a few seconds. The respirator should be worn for periods up to twenty minutes, so that one's behaviour in it becomes perfectly normal and the original nervous feeling is forgotten.

Only after such practice does the respirator become part of oneself, and its wearing a matter of instinct in an emergency. If a person is so unfortunate as to be near a bomb containing a lethal non-persistent gas when it falls, his death or survival is a question of how few seconds it takes to put on the mask. The cloud of gas is very deadly for some hundreds of yards down a street in the direction of the wind, the length of the most dangerous zone being greatest in narrow streets. Further, everyone should have a clearly thought-out plan in their minds what they are going to do should they encounter gas; this will have to be varied according to circumstances. For example, if they are splashed with a few drops of liquid blister gas the time available to prevent a bad burn is short—a matter of five minutes. A clear plan to enter the first house, drop clothing on the doorstep and wash vigorously with soap and warm water, will prevent them becoming a casualty.

The respirator as a filter of poisoned air depends on the outstanding property of suitably activated charcoal to absorb organic vapours: the charcoal is supplemented by a pad able to hold back the finest particles of dispersed substances. The respirator is the result of prolonged study by experts, aided by the leading men of science. It is an all-purposes defensive weapon as nearly perfect as anything which is mass-produced in such enormous numbers can be. It is carefully tested in the course of manufacture, and is considered to give full protection against any war gases in the concentrations in which they are likely to be encountered by a civilian. It is not exhausted by a single encounter with gas, but should continue effective for many months. It may well be that when a respirator is put on in gas, and however quickly, it will enclose a little of the gas, which will cause irritation during the first minute or so. The impulse to tear off the mask must be resisted; also the thought that the mask is not fitting or the filter is letting gas pass. Previous practice will have proved this thought to be wrong, and very soon the respirator will be comfortable. We can do nothing when a high explosive bomb falls near; we can save our homes if we are quick when incendiary bombs fall on them; we can defeat a gas attack if we have trained ourselves in doing it.

Preparation of Fine Chemicals

THE Advisory Research Council of the Chemical Society, in collaboration with the Association of British Chemical Manufacturers, is putting into operation a scheme for organizing the preparation of fine chemicals in Great Britain by part-time volunteer workers in the laboratories of universities, technical colleges, and other institutions. It is essential to the scheme that compounds so prepared must be required for work of national importance and be not available commercially, and that the manufacturers of fine chemicals are themselves unable, or do not find it convenient, to meet the demands. It is intended that preparations should be carried out on a cost-price basis which would include charges for materials, gas, electricity, etc., but not for the workers' services. No profits of any kind will be permitted. Those who wish their names to be added to the list of volunteer helpers in connexion with this scheme should communicate with the General Secretary, Chemical Society, Piccadilly, London, W.1, to whom inquiries for fine chemicals falling within the scope of the scheme may also be made.

Issues and Parties in India

AN English resident in the Punjab writes taking exception to views expressed in these columns in a reference to Mr. L. S. Amery's review of the political situation in India in August last (see NATURE, 146, 255; 1940). He points out that while it is true that there are differences among the Indians themselves, all parties are at one in desiring Home Rule. To attain Home Rule is, or is supposed to be, the purpose of the Indian National Congress; and the preponderancy of the Hindu community in it merely reflects the fact that Hindus are a large majority in the country. It is stated that Moslems are by no means all anti-Nationalist or anti-Congress, and in fact only one party of them is so—the Moslem League, a reactionary conservative body composed of big landlords, title-holders and the like. Indeed, he adds, if a straight vote could be taken without confusing the issue by an appeal to communal fanaticism through such cries as "religion in danger", it is very doubtful if the Moslem League would have a majority over the combined votes of progressive Moslem parties. It was in fact decisively defeated in the last elections in the four provinces which have Moslem majorities. As for the Princes, they are, he says, a relic of feudalism, and do not represent their people. Although Mr. Amery's last offer, having regard to the conditions, was not so bad, it encouraged minorities to believe that however fantastic their claims, the British Government would support them, or at least allow them to hold up Home Rule indefinitely, thus lending colour to the Indian view that Britain does not really mean to give up her power and is playing the game of "divide and rule".

While it is desirable to place on record such a view of the facts of the situation in India in the interest of clearer understanding, it by no means must be held to imply assent among a people with whom religious belief and ritual is all-powerful as in India. The admission that successful opposition to the National Moslem League would depend upon the absence of an appeal to communal fanaticism, demands disruption of the social and religious functions of the individual member of a community in everyday life which is opposed to the whole of Indian culture and tradition. No doubt in many of the more progressive among the people of India, this tradition has become weaker, but nevertheless even among them it persists in some degree. It is for this among other reasons that competent observers have doubted the wisdom or even the possibility of applying the democratic ideal to Indian conditions. On this account, and not with the view of delaying Home Rule by fomenting intercommunal differences, the British Government has sought to accustom Indian ways of thought to respect for the rights of the individual through a compromise which, for the time being, appears to lay undue stress upon the claims of minorities.

Humus and the Farmer

UNDER this title, Mr. G. V. Jacks, deputy-director of the Imperial Bureau of Soil Science, Rothamsted, delivered a lecture on February 12 to the Royal Society of Arts, in which he dealt with the origin of humus, its functions in the soil, and how far shortage of humus-producing organic manures can be made good by other means. Humus is derived from decaying plant and animal residues; it acts by promoting a granular structure in the soil, by supplying energy to micro-organisms, and by providing plant nutrients. In the natural state, vegetation supplies the kind of humus in which it best thrives, but cultivated crops do not supply such an optimum product, so that human intelligence and skill are needed to bring about that biological balance in the soil which is the essence of fertility. A grass cover is especially valuable for producing the granular soil structure that is needed by our basic crops, for these are also grasses, perennial for animal and annuals (cereals) for human consumption.

When a soil has lost its virginal fertility by long-continued arable husbandry, it is best rejuvenated by laying it down to grass for a shorter or longer period. When our ancestors first enclosed the open fields, they nearly always put them down to pasture. Later, when clovers and roots were introduced, mixed farming became possible, animals could be kept throughout the winter and their manure conserved for the land. To-day much stress is laid on the necessity for rejuvenating our cultivated soils by ley farming or alternate husbandry. But the use of grass and plant and animal residues does not suffice in the absence of human skill and intelligence. These attributes became manifest when drilling was first substituted for broadcasting seed, when the art of drainage was developed, and when artificial fertilizers were invented. Such fertilizers can provide all the nutrients plants require, though they cannot produce the granular soil structure effected by humus. Plant humus, on the other hand, will not make a soil fit for permanent agriculture, for a human society makes far greater demands on the soil than does any natural plant community; nevertheless, every scrap of waste organic matter which the land produces should be returned to it.

Soviet Agriculture

IT is stated by "Russia Today" Press Service that the average annual grain crop in the U.S.S.R. for 1937, 1938 and 1939, notwithstanding the severe droughts in the two latter years, amounted to more than 100 million tons, exceeding the 1913 harvest, the best in pre-revolutionary Russia, by one third. The grain crop of 1940 amounted approximately to 112½ million tons. There are 243,000 collective farms in the Soviet Union, embracing 18,800,000 peasant households, or 94 per cent of the total number of peasant households in the country. The Soviet Government has handed over to the collective farms for their free use in perpetuity 940 million acres of land, which represents an average of 50 acres per household. It is estimated that Soviet agriculture employs more than half a million tractors, nearly 170,000 harvester-combines and 200,000 lorries.

Swahili Plant Names

THE demand for Mr. Greenway's modest little "Dictionary of Swahili-Botanical-English Plant Names", having been greater than was expected, has caused the author to prepare a second edition which is nearly three times as thick (Pp. 308+10 plates. Dar es Salaam: Government Printer, 1940. 4*s*.). The format is the same, but there have now been added a separate list of botanical and common English names, a large number of Swahili names, and ten pages of diagrams to illustrate the short glossary of botanical terms. We have noted a few trifling misprints: 'Afromomum' for 'Aframomum', 'tripinnate' for 'bipinnate' (diagram), and 'capitula' for 'capitulum', the drawing for which might equally well serve as a model for an improved garden rake. The printing is excellent, and the author is to be congratulated on providing this enlarged edition of a very useful little book for those in East Africa with little knowledge of botany.

Seventh International Congress of Genetics

THE Proceedings of the Seventh International Congress of Genetics, which was being held in Edinburgh just prior to the outbreak of war, have been issued as a supplementary volume to the *Journal of Genetics*. The difficulties in holding the Congress and the magnificent manner in which the secretariat overcame many of them has already been commented upon in NATURE. The papers, covering a varied and wide field, are published either in entirety or in summary form, under an alphabetical arrangement of author's names. A subject index to these 331 papers increases the value of these Proceedings for those who desire to know recent thought and work in genetics. The production of such a publication, in present circumstances, deserves particular praise, since the authors of some of the papers had to leave the Congress in a hurry and are now out of reach.

Control of Soil-borne Tomato Diseases

PARTIAL sterilization of the soil by heat is one of the most potent methods of control of soil-borne diseases. Amateur growers, however, do not always possess the requisite apparatus, and various chemical treatments have been suggested. Formalin is the most readily available of these, but the liquid has certain disadvantages in practice. W. Brown has briefly reported (*Gard. Chron.*, February 8) good results with an American suggestion to use formalin adsorbed upon an inert carrier such as diatomaceous earth or sawdust. The experiments relate particularly to the damping-off disease of tomatoes caused by Phytophthora fungi, and in some cases a total control of the malady was effected by the use of formalin powder applied to the seed bed when the seed was sown. Such treatment appears to provide a sustained control of damping-off, and not merely to postpone it for a time.

University of London

THE period for which Mr. H. L. Eason was appointed as principal of the University of London terminates on September 30, and the Senate has decided that the post shall not for the present be re-filled. Mr. Eason has held the office of principal since July 1937, having been a member of the Senate from 1911 and vice-chancellor from 1935. The Senate, with the concurrence of the Court, has appointed Mr. Harold Claughton as acting principal as from October 1. Mr. Claughton has been clerk of the Court of the University since the institution of the Court in 1929, and has acted as deputy to the Principal since June 1940. From 1924 until 1929 he was financial officer and secretary to the Senate.

Under an emergency statute made by the Senate, no elections by Convocation of persons to be members of the Senate will be held in the year 1941, and those persons who are due to retire on the second Tuesday in May of this year will continue to be members of the Senate until the second Tuesday in May 1942. Under another emergency statute no elections to the offices of chairman of Convocation and deputy chairman of Convocation are to be conducted before March 1, 1942, and the present holders of these offices will continue in office until the tenth day of May 1942.

DR. J. H. Gray has been appointed, as from May 1, to the University chair of anatomy tenable at St. Mary's Hospital Medical School. Since 1937 he has been senior demonstrator in anatomy at University College.

The following titles have been conferred in respect of posts held at the College indicated: professor in dental surgery on Dr. E. C. Sprawson (London Hospital Medical College); reader in mathematics on Dr. Theodor Esterman (University College) and on Mr. A. C. Stevenson (University College).

The Worshipful Company of Clothworkers has established a fellowship for graduates in science in the University. The fellowship is to be known as the "William Gilles Fellowship in Science" and will be open to internal or external graduates of the University. The award will be made biennially and will be of the value of about £220.

The degree of D.Sc. has been conferred on: Mr. P. A. I. Gorer, of Guy's Hospital Medical School; Mr. D. W. W. Henderson, of the Lister Institute of Preventive Medicine; and Mr. R. W. Haines, of St. Thomas's Hospital Medical School.

University of St. Andrews

THE "University of St. Andrews: Handbook of the United College" published by the St. Andrews University Press is a neat little brochure clad in the scarlet of the well-known gown. The University stands first in Scotland in age, and the latest of its senior foundations, the College of St. Mary, is of 1537. That of 1450 is still represented by the tower of St. Salvator. conspicuous from the sea. The unique graduate rolls date from 1413. Quaint customs survive such as Kate Kennedy Day. There was a period of decay which Johnson saw; but the College revived to produce its full share of eminent men and a reputation for research in chemistry. The successful rigour of the past is shown by a student who entered in 1819 and lived for more than six months on little more than £14. Games were prohibited in the monastic College of St. Leonard except a weekly visit to the links in the company of a Master. "It takes a heid to play golf," as a famous exponent of it once remarked. Considerable use has been made of the book on "Historic St. Andrews and Its University" by Prof. J. Read, professor of chemistry there, while Mr. John Hinton Read has provided most of the photographs for the effective illustrations.

Announcements

PROF. J. B. CONANT, president of Harvard University, who is visiting Great Britain to discuss scientific collaboration with the United States, has had conferred on him the honorary degree of doctor of science of the University of Oxford.

PROF. EDWARD A. DOISY, professor of biochemistry in the School of Medicine of St. Louis University, has been awarded the Willard Gibbs Medal for 1941. This medal, one of the highest distinctions in chemical science, is given annually by the Chicago Section of the American Chemical Society. Dr. Doisy accomplished the isolation of vitamin K from dried alfalfa leaf meal and putrefied sardine meal in 1939. Before that he had, in 1929, isolated theelin, female sex hormone and, in 1936, dihydrotheelin, another sex hormone.

DR. DIRK BROUWER, associate professor of astronomy at Yale, has been promoted to a full professorship, and has been appointed director of the Yale University Observatory in succession to Dr. Frank Schlesinger, who retires in June next.

THE supply of radium amounting to 6 gm. of the Paris Curie Institute, which had been sent into the country before the entrance of the Germans, has now been returned to Paris.

AN Institute for Tropical and Subtropical Diseases has been opened at Modena under the direction of Prof. Giovanno Serra, formerly director of the hospitals at Albertville in the Belgian Congo.

THE National Book Council, 3 Henrietta Street, London, W.C.2, is sending out lists of books specially selected for use in factories and workshops. The first issue consists of two lists in a portfolio; these lists will be supplemented at regular intervals. The titles, publishers and prices of books are mentioned, and a brief note on each entry indicates its scope. The lists are being sent free of charge to some 5,000 engineering firms in Great Britain.

ERRATUM. The title of the book by Prof. M. G. Mellon reviewed in NATURE of March 15, p. 310, was incorrectly printed as "Chemical Productions"; the book, which is published by the McGraw-Hill Book Co., Inc., is entitled "Chemical Publications".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

An Interesting Sidelight on the Causes of Coloration in Butterflies

IMMS[1] states that "pigment very commonly co-exists with structures that are, in themselves, colour producing" and that "combination colours are much more prevalent among insects than colours solely due to structural features . . . Iridescent colours are very often devoid of the presence of all pigment excepting black or dark brown . . . as a rule a background of this nature is necessary to the production of the brilliant and intense structural blues. . . ."

Butterflies of the Oriental genus Euplœa well exemplify this phenomenon, often more strongly in the male sex, and a specimen of *E. tulliolus aristotelis* Moore from British North Borneo in the Oxford University Museum throws interesting light upon it.

The butterfly, a very fine fresh male, had been seized and released by a bird, and the nip of the beak has left a conspicuous ∧-shaped 'beak-mark' on the right fore wing extending from the hinder angle forward, near to the outer margin, to beyond vein 4; it is, of course, clearly shown on the under surface also. Such 'beak-marks' have long been a subject of special study at Oxford[2], where a large collection of specimens has been gathered together, but the interest of the one in question is that it illustrates Mason's remarks on these blue reflections[3]. He examined species of butterflies with blue-green bars, etc., and found that "the remainder of the surface is dull brown except in certain positions, when it is purple to blue-green, so that as the wing is inclined this colour flashes out. The scales in these brown to blue areas are not particularly convex [as they are in the blue-green areas] but are markedly inclined to the surface of the wing, so that the tip is higher than the base and the scale makes an angle of thirty degrees with the plane of the wing. The reflection from these scales is specular, and they therefore appear bright only when the angle of incidence of the illuminating beam and the angle of reflection along the line of vision are equal.

"The two factors render the reflection colour visible when one looks along the grain of the wing, but against the grain there is no reflection and the effect is that of the brown pigmentation. . . ."

I have not been able to find a reference to Euplœa in this connexion, but the specimen under consideration shows the same phenomena; the whole wing is brown (or purple) except for small submarginal white spots. But the linear imprint of the bird's beak has acquired a colour different from that of the rest of the wing, being more blue than purple and not disappearing when the wing is tilted.

The microscope shows, first, that the pressure of the beak has ruptured the saccular scales so that the pigmented, brown, contents have escaped and dried in minutely granular masses. These, especially noticeable at the apex of the beak-mark, reflect strongly deep blue rather than purple.

Secondly, scales have been (*a*) displaced, (*b*) flattened along the line of the beak's contact, and being in different positions from the normal, tilted, scales, their striated surfaces reflect differently, so that the mark for this reason shows purple when the rest of the wing does not.

I am indebted to my friend Mr. E. B. Ford for help in the elucidation of this interesting result.

Effect of Temperature on the Mutation Rate of an Unstable Gene in *Portulaca grandiflora*

THERE are few data on the relation between temperature and natural mutation rate, though obviously this is important in formulating any concept of the nature of genes. Delbrück *et al.*[1] have examined the consequences of regarding mutations as simple chemical changes in molecules, and have pointed out that if the 'life' of an allele be of the order of months or years, then the mutation rate may be expected to have a Q_{10} of the order of 5. Experiments by a number of workers (reviewed by Stubbe[2]) do in fact show a high Q_{10} of that order, for genes having 'normal' mutation rates (1 in 10,000 or more life-cycles) and particularly for the collective class of lethal mutations in the *X*-chromosome of *Drosophila melanogaster*.

A frequently mutating gene on the other hand, the miniature-3-gamma in *Drosophila virilis*, has been shown by Demerec[3] to be apparently but little affected by temperature differences, and Rhoades reported at the Seventh International Congress of Genetics[4] an apparent decrease in mutations of the gene *dt* (in conjunction with another factor) in *Zea Mays* with higher temperature. On the view proposed by Delbrück, even unstable genes like these should have a Q_{10} of not much less than 4, a value which it seems impossible to reconcile with Demerec's data, after making the fullest allowance for experimental inaccuracies.

We have carried out an experiment with a mutable gene which produces coloured spots on the petals and stems of *Portulaca grandiflora* (Ikeno[5]). Four clones were grown, and one representative of each was kept in a thermostatic chamber for six weeks.

The temperatures used were 25°, 30°, 35° and 40° C. The number of mutations was estimated by taking four shoots about 10 cm. long from each plant and observing the number of spots and their size. The results are given in Table 1, in the form of the number of mutations per cm. length of stem, of 2 mm. diameter. A correction was made for large spots, since in the coloured areas no more mutations occur. (One clone produced few mutations in the stem epidermis and is excluded from the table.) Altogether 630 mutations were counted.

TABLE 1.

Clone	25°	30°	35°	40°
1	2·89	2·05	1·07	0·54
2	2·92	2·39	1·09	0·60
3	2·75	2·22	0·86	—

There is a consistent, and statistically very significant, apparent reduction in mutation rate with increasing temperature.

It is of interest to consider mutation rate not as a function of time, as is done in Table 1, but of the number of cell divisions. The areas of epidermal cells were measured, and it was found that cell size increased with temperature throughout the range tested, though maximum stem elongation took place at 35°. In Table 2, values from Table 1 have been multiplied by corresponding cell areas; they are also adjusted by a common factor making the means of the two tables equal, for easier comparison.

TABLE 2.

Clone	25°	30°	35°	40°
1	1·70	1·98	1·25	0·96
2	2·42	2·14	1·28	0·71
3	3·45	2·59	0·90	—

These values are proportional to the mutation rate per cell; an analysis of variance of the data on which they are based shows that the effect of higher temperature in reducing mutation rate is still highly significant. Moreover, petals spots, including those from clone 4, though difficult to analyse quantitatively, show the same effect.

At this stage we can offer no explanation for this rather paradoxical result. It is very desirable to know how general it is among mutable genes.

As an example of the kind of complication which is met with in studying the effect of temperature, we wish to place on record that, in Portulaca, higher temperature produces less acid cell sap, as is the case with certain Crassulaceæ. It is conceivable that pH influences mutation rate, and temperature effect might thus be indirect; altered acidity is likely to be but one of many physiological conditions changed by temperature.

We hope it may be possible to describe these experiments fully later.

Determination of pH in Wood

IN the course of certain researches in progress at this Laboratory it became necessary to find a satisfactory method of determining potentiometrically the pH of the moisture present in wood when the latter is in the air-dry condition, that is, at a moisture content of between approximately 5 and 20 per cent. Most pH determinations in the study of wood are applied to aqueous extracts prepared under standard conditions, and whilst the results so obtained are of value for some purposes, we have found that it is only when a wood exerts a relatively strong buffering action that an extract prepared, for example, by leaching 1 gm. of the powdered substance with 20 ml. of distilled water, can have a pH approaching closely in numerical value to that of the moisture of condition present in the wood substance prior to extraction.

Species	Moisture content at 60 per cent R.H. (% oven-dry weight)	*Mp*H
Mugongo *Ricinodendron rautenenii* Schinz.	8·14	6·69
Balsa *Ochroma* sp.	6·81	5·54
Beech *Fagus sylvatica* L.	8·93	5·21
Birch *Betula lutea* Michaux	9·65	4·62
Teak heartwood (*Tectona grandis* L.)	7·55	4·50
Oak sapwood *Quercus* sp.	11·11	4·40
Scots pine *Pinus sylvestris* L.	6·21	4·27
Sitka spruce *Picea sitchensis* Carr	10·25	3·98
Douglas fir *Pseudotsuga taxifolia* Brit. Sample (1)	8·70	3·67
Oak heartwood *Quercus* sp. Sample (1)	11·73	3·50
Oak heartwood *Quercus* sp. Sample (2)	10·86	3·16
Douglas fir *Pseudotsuga taxifolia* Brit. Sample (2)	9·77	2·89
Western red cedar *Thuja plicata* D. Don	8·27	2·46

It has been found by one of us (S. A. B.), however, that the pH of the water used to extract a sample of wood flour can be so adjusted beforehand that it undergoes no change when mixed in any proportions with the wood substance at room temperature. Thus, in short, the pH of the moisture of condition of the wood, which we propose to term the 'moisture pH', or simply '*Mp*H', is numerically equal to that of the solution containing free hydrogen ions which, when added to it under the conditions stated, undergoes neither a net loss nor gain of hydrogen ions. *Mp*H values, determined by means of the glass electrode, of samples of a number of wood species are given in the accompanying table.

It is hoped that full details about this new determination and some of its possible applications will be published elsewhere in the near future.

True Surface Densities of Protein Films

It has been disputed[1] whether Gorter's[2] method of spreading proteins to form surface films can really give a homogeneous film unless either (*a*) very dilute solutions are used for spreading, or (*b*) very long times, from 1 to 24 hours, are allowed before the force-area measurements are made. In the case of gliadin films, however, a vindication of the earlier method has been published[3] and it appears from the figures quoted here that equilibrium is achieved within a very few minutes after the film is spread.

Further measurements suggest, however, that although, as Jenkins and Taylor show, the surface-density figures for longer times are lower because of contamination of the surface, there is some merit in performing these measurements. The figures in the accompanying table which have been obtained for zein, show that the initial drop in surface density with time is much more rapid than the later fall, but not sufficiently rapid to avoid some contamination.

Table 1.

Time (mins.)	5	5	5	10	10	30	30	60	150	290	420	1400
$d \times 10^7$	1·32	1·40	1·35	1·31	1·33	1·26	1·32	1·19	1·16	1·10	1·07	0·89
Mean d	1·36			1·32		1·29						

It is clear that the surface density of the completely spread, but uncontaminated film, is obtained by extrapolating the shallow part of the curve to zero time, when a value of $1 \cdot 21 \times 10^{-7}$ is obtained for d. A somewhat similar curve is obtained, though with less regularity, for gliadin from the averaged figures of Jenkins and Taylor.

Measurements on hen's egg albumen show a similar trend. The spreading here seems to be considerably slower, and at least half an hour is required for complete spreading. The protein films are fully reversible and can be recompressed an indefinite number of times, without alteration in the shape of the compression curves. The figures for four different spreadings are:

Table 2.

Time (mins.)	10	15	45	60	80	90	180	Extrap. density
(1)		1·20		1·10		1·06		1·13
(2)	1·37		1·19			1·13	1·10	1·165
(3)	1·13		1·09			1·06		1·125
(4)	1·14		1·07		1·02			1·13

The extrapolated densities almost entirely smooth out the fairly wide variations between individual measurements at short spreading times, and the mean value of 1·14 is closely similar to results obtained in the same way for gliadin and zein.

All the measurements were made on a substrate of $0 \cdot 01N$ sulphuric acid at room temperature.

There seems to be little doubt that this compromise between the methods of Mitchell and Jenkins and Taylor is the most satisfactory means of overcoming irregularities due to accidents of contamination and initially uneven spreading of the protein film.

Diffuse Reflexion of X-Rays

Prof. G. E. M. Jauncey[1] derives the formula:

$$\varphi_{mB} - 2\theta_B = 2(i - i_B)\sin^2\theta_B. \qquad (1)$$

for the relative position of a Bragg reflexion and the so-called "modified reflexion". The symbols are defined as follows: i is the glancing angle of incidence on the crystal plane for which $\theta_B = i_B$ is the Bragg angle: φ_{mB} is the angle between the incident ray and the direction of scattering of the modified reflexion: $i - i_B$ is supposed to be small. The disposition of the incident ray I, the scattered ray S, and the crystal plane are shown in Fig. 1. Prof. Jauncey deduces (1) from a formula of Sir William Bragg's, and it is obtained from quite different assumptions by Raman and Nath and by Zachariasen. In fact (1) is only an approximation to a formula due to Faxén which may be put in the form:

$$d \sin \varphi = \lambda \cos (\varphi - i), \qquad (2)$$

where d is the spacing of the plane for which the Bragg angle is θ: $\varphi (= \varphi_{mB})$ and i are as shown in Fig. 1. Using Bragg's Law to eliminate d and λ from (2),

$$\sin \varphi = 2 \cos (\varphi - i) \sin\theta. \qquad (3)$$

That (3) is an exact form of (1) may be proved by varying i and φ for constant θ, giving

$$\cos \varphi \, \delta\varphi = -2 \sin\theta \sin (\varphi - i).(\delta\varphi - \delta i). \qquad (4)$$

When the angle of incidence changes from θ to i, $\delta i = i - \theta$, and at the same time the angle of scattering changes from 2θ to φ, so that $\delta\varphi = \varphi - 2\theta$: if i is nearly equal to θ, $\varphi = 2\theta$ and $\varphi - i = \theta$ approximately, so that (4) gives

$$\cos \varphi.(\varphi - 2\theta) = -2\sin^2\theta. \quad (\varphi - 2\theta - i + \theta)$$
$$\text{or } \varphi - 2\theta = 2\,(i - \theta) \sin^2\theta, \qquad (5)$$

which is identical with (1) when the suffixes are introduced.

The geometrical significance of Faxén's formula (2) is shown in Fig. 2. Here O is the origin of reciprocal space, B the Bragg spot, and P the modified reflexion. Faxén's formula states that P lies in the line joining B to C, the centre of the sphere of reflexion. The angles i and φ are shown on the diagram, CN being normal to OB. The formula follows at once from the geometry of the triangle OCB.

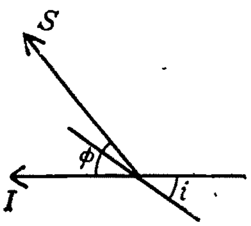

Fig. 1.

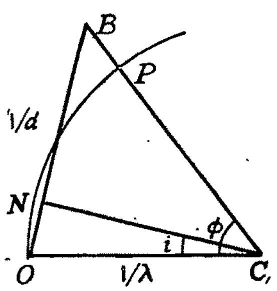

Fig. 2.

The physical interpretation of Faxén's formula is that the surfaces of constant intensity surrounding the Bragg points are spheres: I have found that the pattern given by aluminium[2] conforms to this rule, but at the time had not observed that this amounted to a verification of Faxén's formula. The function used by Prof. Jauncey in arriving at (1) has the same property.

Influence of Œstrogens and Androgens on Glycogen Storage in the Fasting Rat

Janes and Nelson[1] have observed that glycogen storage in rats treated daily with diethyl-stilbœstrol for five days or more is at an abnormally high level. We have investigated the influence of œstrogens and other sex hormones on glycogen storage; and also on the insulin content of the pancreas (*cf.* Griffiths and Young[2]). Data are given in Table 1, including the liver and muscle glycogen contents, after a fast of approximately 18 hr., of rats carrying subcutaneous tablets of various substances for two weeks. These results show that œstriol and œstradiol resemble diethyl-stilbœstrol in promoting glycogen storage under these conditions, although œstrone and testosterone do not. It appears that the influence of these substances on liver glycogen under such conditions is to some extent paralleled by their action in causing enlargement of the liver and an increase in pancreatic insulin; it seems possible that the latter phenomenon is secondary to the increase in glycogen storage.

Table 1.

Influence of Œstrogens and of Testosterone on the Storage of Glycogen and of Insulin in the Rat.

Substance implanted	Number of rats in group	Blood sugar mgm./100 c.c.	Liver weight gm./100 gm. body weight	Liver glycogen gm./100 gm.	Muscle glycogen gm./100 gm.	Pancreatic insulin	
						u./100 gm. body weight	Percentage increment above control
Cholesterol (control)	30	108	3·82	1·13	0·37	0·70	—
Diethyl-stilbœstrol	30	109	5·79	2·27	0·41	0·95	36
Œstriol	10	115	5·13	2·32	0·39	0·93	33
Œstradiol	10	113	4·48	1·67	0·43	1·05	50
Œstrone	20	105	4·40	0·77	0·42	0·68	nil
Testosterone	10	99	3·68	0·69	0·44	0·68	nil

Table 2.

Influence of Diethyl-stilbœstrol on Glycogen Storage in the Fasting Rat.

Treatment of rats	Amount injected	Number of rats in group	Blood sugar mgm./100 c.c.	Liver weight gm./100 gm. body weight	Liver glycogen gm./100 gm.	Muscle glycogen gm./100 gm.
Killed initially	—	30	97	2·86	0·85	0·31
Injected and fasted 30 hours . .	Nut oil only	35	95	2·87	0·57	0·31
,, ,, ,, ,, ,, ...	0·10 mgm.	20	93	2·94	1·04	0·32
,, ,, ,, ,, ,, . .	1·00 mgm.	25	99	3·01	1·96	0·34
,, ,, ,, ,, ,, . .	10·00 mgm.	20	109	3·98	2·04	0·30

When rats were fed on cellulose for 30 hours in order to deplete the glycogen stores, and were then given a single subcutaneous injection of various substances in nut-oil, an increase in liver glycogen was found to occur, in some instances, during a subsequent 30-hour fast. The results with different doses of diethyl-stilbœstrol in experiments of this type are shown in Table 2, and indicate that a single injection of 0·1 mgm. of this substance is capable of increasing the liver glycogen content of the fasting rat under such conditions. No obvious change in muscle glycogen content or in blood sugar level was observed in these experiments, with the possible exception of those in which 10 mgm. of diethyl-stilbœstrol was used. Again the increase in liver glycogen content was accompanied by an increase in liver size; it should be mentioned that the treated rats lost little, if any, more body-weight during the fasting period than did the control animals. Œstradiol and œstriol were found also to induce an increase in the liver glycogen content of the fasting rat under similar conditions, a property in which they resemble hormones of the adrenal cortex[3,4].

These experiments show that some œstrogens can exert a profound influence on carbohydrate metabolism, inducing an increase of pancreatic insulin and a positive increase, not merely diminished loss, of liver glycogen in the fasting rat, the latter being apparently not due to a transfer of glycogen from the muscles to the liver (Table 2).

RESEARCH ITEMS

Early Cult Figures from the Indus Valley

Seals showing the figure of an unidentified deity found at Mohenjo-daro have been identified tentatively by Sir John Marshall as Śiva-Paśupati, but Saletore regards them as representations of Agni. The latter would weigh in favour of the Aryan hypothesis of Harappa cultural origins in the Indus Valley. Agni has no counterpart in the pre-Aryan cultures known to us. The argument in favour of the identification with Siva rests in part on the character of the trident-like head-dress, which Saletore maintains does not represent Siva's trident. This head-dress is regarded by A. Aiyappan (*J. R. Asiat. Soc. Bengal, Letters*, **5**, 3; 1940) as the key to the understanding of the nature of the religious representation intended by the seals on which the figures appear. Taken as a group, there can be little doubt that the sculptor intended to show two, not three, horns. Agni is shown as three or four horned, and though he is likened to various animals such as bull, steed, winged bird, or goat, nowhere is there any suggestion that he should have a pair of buffalo or bison horns. To the ethnologist the head-dress is full of interest. Its various forms find counterparts in the head-dresses of modern Indian tribes, the Bison-horn Gonds, the Koyas and Savaras of the Eastern Ghats and the Naga tribes of Assam. That of the Kalyo Kengyu warrior of the Naga Hills is almost a modern copy of that of the Mohenjo-daro figures. The meaning of the latter can only be gathered if considered from the ethnological angle, though identity of significance must not be postulated. Nevertheless, it would appear from modern instances that there are rites allocated with fertility and buffalo cults which still exist among many tribes and even Hindu castes in a vestigial and attenuated form but may well have been a living cult when the culture of Mohenjo-daro flourished. The Mohenjo-daro deity does not possess many attributes of the Siva of modern Hinduism, but his most fundamental qualities are suggestively indicated—the horns suggesting the trident and fertility, the phallic aspect and the pose and surroundings of Siva's yogic characteristics.

Studies on Reef Corals

Vol. 2, No. 1, of the Palao Tropical Biological Station, Tokyo, 1940, includes several papers on reef corals dealing with growth, biochemistry and environment. S. Motoda contributes three: "A Study of Growth Rate in the Massive Reef Coral *Goniastrea aspera* Verill", "The Environment and the Life of the Massive Coral, *Goniastrea aspera* Verrill", and "Comparison of the Conditions of Water in the Bay, Lagoon and Open Sea in Palao". K. Hosoi in his work on the biochemistry of the coral has investigated the "Occurrence of Iodine in the Polyp of *Funigia actiniformis* var. *palawensis* Döderlein, the Distribution of Nitrogen in the Protein of the Polyp, and the Amount of Calcium and Carbonate in the Skeleton". N. Abe writes on the growth of the same species and its environment. Interesting observations are made by Motoda on Goniastrea in which he finds that the actual living polyps are eaten by certain fishes. This coral when transplanted to the reef margin was much damaged by being bitten by fishes, although this did not take place in its natural habitat. The author also observed that the reef fishes in the aquarium of the Laboratory frequently pick the living polyps of the reef corals until these lose the soft bodies and are killed. Also he states that it is seen when diving that many small reef fishes are picking upon the surface of the living corals. Although, as other observers have maintained, it may be that the fishes are feeding on the algæ growing on the corals, these new observations appear to show that the fishes do eat the actual polyps. In addition to the studies on corals there is a paper on the "Oligochæta from the East and West Carolines, South Sea Islands" (I) by S. Ohfuchi, and one on the "Luminescence of the Fishes belonging to the Family Leiognathidæ of the Tropical Pacific" by Y. Haneda.

Measurement of Solar Radiation

A paper on the measurement of solar radiation for ecological work has recently appeared (Bericht über das Geobotanische Forschungsinstitut Rübel in Zürich für das Jahr 1939. Von E. Rübel und W. Lüdi. Pp. 152. Zürich: Geobotanische Forschungsinstitut Rübel, 1940). It describes a dozen different sorts of commercially produced apparatus (mostly unfamiliar to the reviewer) some intended to measure the total energy of radiation, others particular wave-lengths, and yet others the total energy over a period. The principles and limitations of each apparatus are discussed, and should enable a reader with a definite problem to choose his apparatus. The other papers deal with the changes observed in some quadrats of alpine grassland over a century, the alpine vegetation of Mt. Etna (both treated statistically), and a very brief paper on pollen analysis.

Nomenclature of Fungal Genera

Mycologists, as the custodians of nomenclature in one of the most dynamic groups of living organisms, have the duty of critical review of their taxonomic groups, as knowledge about the systematics of their subject increases. A committee of the British Mycological Society has been appointed to perform this work, and the third of its "Nomina Generica Conservanda" has recently been published under the name of E. M. Wakefield, secretary to the Committee (*Trans. Brit. Mycol. Soc.*, **24**, Pts. 3 and 4, 282–293; Dec. 1940). This deals, among other questions, with the nomenclature of Daldinia, Dothidella, Agaricus and Psalliota, Septoria and Ramularia. It is necessary that someone should work through the mass of what would be dreary detail for most workers. The recommendations of the committee are usually trenchant; only in its consideration of Agaricus versus Psalliota has it lost the determination to return from the established Psalliota to the valid Agaricus.

Intergeneric Hybrids of Saccharum

E. K. JANAKI-AMMAL (*J. Gen.*, **41**, 217–254; 1941) has described intergeneric hybrids of Saccharum with species of Narenga, Erianthus, Sorghum, Zea, Bambusa and Imperata. The variety and number of these hybrids together with their morphology and fertility provide astonishing and most valuable information regarding the possibilities of hybridization involving a high polyploid, such as is found in Saccharum. The present paper describes: (1) the cross *S. spontaneum* ($2n = 112$) with *Erianthus ravennæ* ($2n = 20 + f.$). The F_1 has 66 chromosomes and is fertile and gives rise to diploids, triploids and tetraploids. Segregation of Erianthus characters occurs among the diploids. The chromosomes of *S. spontaneum* form bivalents,by autosyndesis in the F_1, and may form trivalents with some of the chromosomes of Erianthus. The sugar content of the diploid F_1 is lower than in *S. spontaneum.* (2) The cane *POJ*2725 arose from continued crosses of *S. spontaneum* with *S. officinarum* ($2n = 80$) and has $2n = 106$. When this plant was crossed with *Imperata cylindrica*, thirty-five seedlings with fairly high sugar content were obtained. These were (*a*) vegetative seedlings and resembled the maternal parent, (*b*) selfed or parthenogenetic seedlings with 108–112 chromosomes, (*c*) triploid self seedlings ($2n = 156$), and (*d*) true hybrids ($2n = 120–134$). Seedlings from this last category segregate for Imperata characters. (3) In crosses of *S. officinarum* with *Zea Mays* ($2n = 20 + 1B$), one hybrid which survived had 52 chromosomes and remained dwarf and has not flowered. Novel characters, not present in the parents, are seen in the hybrid.

South African Geology

THE country around Potchefstroom and Klerksdorp is one of the most interesting districts of the Transvaal, including, as it does, all the principal geological formations from the Witwatersrand to the Coal Measures of the Karroo, with the exception of the Waterberg system. The area has been described in detail by L. T. Nel and others in the "Explanation of Sheet No. 61", recently published by the Geological Survey of South Africa. The extraordinarily thick Witwatersrand system was accumulated above a denuded and subsiding surface of the Older Granite, occasional pebbles of which have been found in the lower Witwatersrand grits. A second unconformity comes between the Witwatersrand and the Ventersdorp lavas and is particularly marked in the Klerksdorp area. A third break is found at the base of the Transvaal system, which was deposited on a comparatively flat surface like that of a peneplain. After the close of this period the older rocks were subjected to regional folding and erosion. Long afterwards the Coal Measures of the Karroo system were deposited. Most of these flat-lying beds have been since removed by denudation, and the underlying structure is seen to be a major syncline of Transvaal sediments with older formations arched up on both sides. The axis curves round the Vredefort dome, part of which appears in the south-eastern corner of the area mapped. As the Older Granite which occupies the central portion of the dome is older than the Witwatersrand system, it must have been raised as a solid plug through a vertical distance of thousands of feet. The origin of this unique structure, with its associated overturning of the surrounding rocks and the production of pseudotachylyte, has aroused wide discussion. Dr. Nel, however, is obliged to admit that a complete solution of the tectonic problem cannot yet be claimed. The memoir contains an important review of the magnetic anomalies in the Witwatersrand system, petrological details of the many igneous rocks of the area, and a full account of the economic products, with special reference to gold and water supplies.

Heavy Oxygen

THE fact that oxygen in air has a somewhat higher atomic weight than that in water was discovered by Dole in 1935, and the difference has since been measured by several observers. There is still some uncertainty attached to the results owing to (1) the still imperfectly known degree to which different natural waters differ in density, (2) the possibility of variation of the same source of water at different times, (3) the possibility of different isotopic separations during the purifications. The rapid and complete exchange of oxygen in many inorganic salts with the solvent water suggests that the Dole effect could be measured by this method, and some experiments with sodium dichromate have been reported by O. R. Alexander and N. F. Hall (*J. Amer. Chem. Soc.*, **62**, 3462; 1940). Exchange experiments were made with water synthesized from atmospheric oxygen and Lake Mendota water as standard. The results showed that the excess density due to air oxygen is $7{\cdot}65 \pm 0{\cdot}2\ \gamma d$ with Madison city water regarded as normal and $7{\cdot}1 \pm 0{\cdot}2\ \gamma d$ with Lake Mendota water regarded as normal. The oxygen of the dichromate was somewhat heavier than that of the lake water and much lighter than that of the air water. These experiments thus substantiate the Dole effect.

Reactions of Atoms and Free Radicals in Solution

IT appears that substitution and displacement reactions in organic chemistry fall into two groups in which the reaction proceeds by (A) an ionic or polar mechanism and (B) atomic or free radical. The photochemical (peroxide catalysed) chlorination of a hydrocarbon is a familiar example of a B-type reaction with two possible mechanisms with the chlorine atoms produced in the primary process:

$$\begin{array}{ll} (B_1) & (B_2) \\ Cl\cdot + RH = RCl + H\cdot & Cl\cdot + RH = R\cdot + HCl \\ H\cdot + Cl_2 = HCl + Cl\cdot & R\cdot + Cl_2 = RCl + Cl\cdot \end{array}$$

The substitution of chlorine for hydrogen on the asymmetric carbon atom of an optically active compound by process B_1 would result in Walden inversion with retention of optical activity, whilst the reaction according to process B_2 would yield an optically inactive *dl* product if a free radical with an appreciable half-life period is formed. H. C. Brown, M. S. Kharasch and T. H. Chao (*J. Amer. Chem. Soc.*, **62**, 3435; 1940) have investigated the photochemical chlorination of primary active amyl chloride from this point of view. Six possible isomers result from the introduction of a second chlorination, and it was necessary to isolate the 1,2-dichloro derivative and examine it for optical activity. This could be done by careful fractional distillation, and the product was found to be optically inactive, thus indicating that substitution occurred by process B_2. The other products of the reaction were also investigated, and the two isomers not previously reported were isolated.

PARALYSIS PRODUCED IN WHITE RATS BY A RACHITOGENIC DIET

By Dr. H. A. Shapiro,

Biological Control Laboratories, Union Health Department, Cape Town

DURING the course of rachitogenic experiments with white rats it was noticed that if the rats were kept for prolonged periods on Steenbock's No. 2965 diet, a progressive paralysis of the hind limbs developed.

The diet consisted of the following :

Whole yellow maize (finely ground)	76	per cent
'Energen' gluten	20	,,
Calcium carbonate	3	,,
Sodium chloride	1	,,

Young rats of either sex weighing 40–60 gm. when placed on this diet developed severe rickets in three weeks. This was obvious by swelling of the wrists and the knees, and was further demonstrated (*a*) in sections of the distal halves of the radius and the ulna stained by the usual silver nitrate method, (*b*) by X-ray studies of the bones.

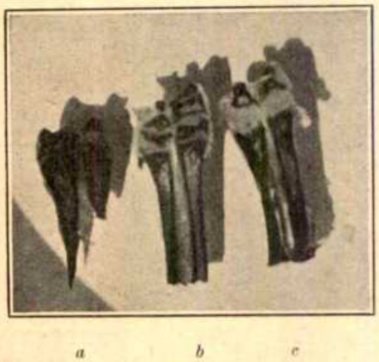

Fig. 1.

a, NORMAL BONE (RADIUS AND ULNA) ; *b*, PARTIAL HEALING ; C, SEVERE RICKETS.

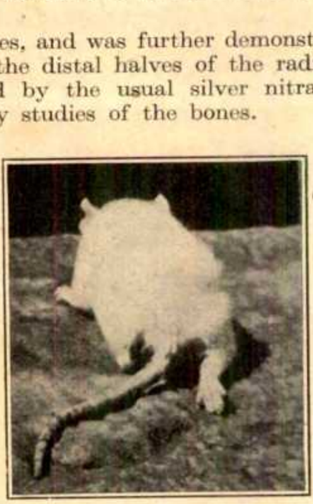

Fig. 2.

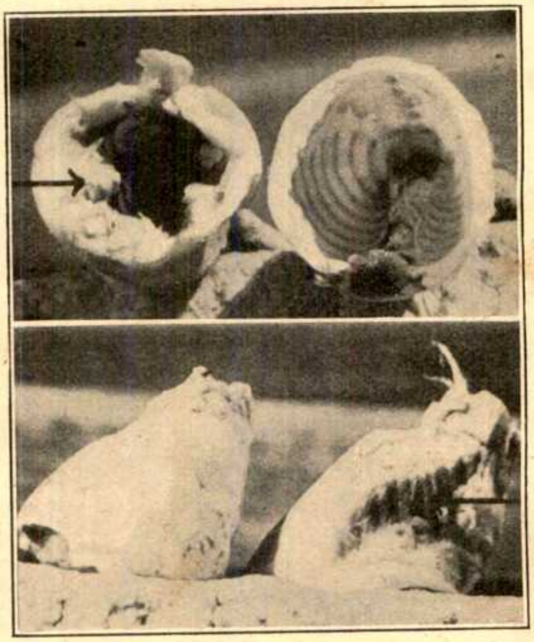
EXTENSOR WEAKNESS OF RIGHT FOOT.



INFERIOR (ABOVE) AND LATERAL (BELOW) ASPECTS OF CHEST. THE RICKETY CHEST, SHOWING COLLAPSE OF RIBS, IS ON THE LEFT ABOVE, AND ON RIGHT BELOW.

When the animals were kept for considerably longer on this diet the rickets became much worse (Fig. 1*c*) and after 6–9 weeks the earliest signs of weakness of the hind limbs developed. This consisted of a widening of the base, especially well marked in some of the animals at rest, together with a well-defined foot-drop (Fig. 2) in either or both feet due to weakness of the extensor ('antigravity') muscles and an inco-ordination of the gait. The weakness of the hind legs spread progressively until after 7–10 days the animal was unable to stand on all fours. It then progressed by pulling its hindquarters along with the aid of its forelimbs, which showed no signs of weakness in spite of the severe degree of rickets.

With the full development of the paralysis other signs of a cord lesion appeared, namely, urinary incontinence and a persistent priapism.

The paralysis was not flaccid although there was considerable wasting of the thigh muscles, especially of the extensors. Definite tone was maintained in the flexors (hamstrings) and in the tail. Such animals showed maximal rachitic signs ; for example, the development of a marked degree of 'pigeon chest' due to the falling in of the ribs (Figs. 3 and 4). In all, a total of eight animals was placed on this diet in the course of five months. All eight animals developed this paralysis.

Autopsy of three of the animals failed to reveal any macroscopic hæmorrhages in the nervous system. The marked atrophy of all the thigh muscles, especially of the extensors, was confirmed.

There was a superabundance of carotene in the diet (yellow maize) and there was no evidence in the eyes or the teeth of any vitamin A deficiency. The colour of the teeth was, if anything, better than that of the normal control animals. This point is of importance, since Irving and Richards[1] have reported that degenerative changes are observed in the nervous system of rats on a vitamin A deficient diet. In their experiments, however, the chief changes were seen in the medulla.

At no stage in the development of the paralysis was there any evidence of a peripheral neuritis such as might be attributable to an aneurin (vitamin B_1) deficiency, namely, pain and tenderness of the affected limbs when these were palpated. Moreover, clinically the syndrome of progressive paralysis did not resemble the paralysis produced by vitamin B_4 deficiency in rats[2,3]. B_4 deficiency in rats results in the adoption of a hunched position 'walking high' on the hind-legs with a progressive loss of co-ordination[3].

It appears unlikely that vitamin C can be involved in the production of this syndrome.

α-tocopherol, whether given by mouth or by injection in the form of the acetate, at the stage when foot-drop was noticed, was unable to arrest the steady progression of the weakness.

The possibility still exists that some other component of the E complex may be involved. In view of the fact that whole maize was used it appears unlikely that the diet could have been E deficient, in spite of the fact that clinically the syndrome fairly strongly resembles the picture of vitamin E deficiency. In any event the paralysis is unlikely to be due to an α-tocopherol deficiency.

The possibility remains that the lesions may be due to marked vitamin D deficiency in one of two ways:

(1) Vitamin D may be necessary for the proper nutrition of the nervous system.

(2) Since the paralysis so far has been observed only in severely rachitic rats, the lesion may be secondary to a mechanical complication as a result of the rachitic process having affected the vertebræ, especially in the lumbar region. I am indebted to Dr. N. Sapeika for this suggestion.

It is of interest to note that Greenberg, Boelter and Knopf[4] reported observations on rats on a low calcium diet which accorded with the description of neurological lesions in rachitic rats described by Boer, Arons and van der Ryst[5]. Van der Ryst and Arons[6] also used the Steenbock No. 2965 diet, and they described paralysis and hæmorrhages in the nervous system in 75 per cent of rachitic rats on this diet. They did not conclude, however, that the symptoms were due to lack of vitamin D.

The simplicity and the purity of the diet used in the experiments recorded in this note render it unlikely that the syndrome observed is due to a poison or toxin.

It remains possible that the symptoms resulted from protracted vitamin D deficiency, or that some other vitamin is necessary for the proper nutrition of the nervous system. Although it seems most unlikely that the vitamin E complex is involved here, it should be noted how closely the paralysis described in these experiments resembles the paralysis seen in the hind limbs in vitamin E deficiency. On this rachitogenic diet the forelimbs were never affected. This is unlike vitamin E deficiency paralysis.

Further studies on the histology of the nervous system and the affected muscles, as well as of the prophylactic role of vitamin D and certain other vitamins, are in progress.

I wish to thank Prof. W. F. Rhodes for his interest in this investigation. The photographs are 'stills' taken from a moving picture record made by Mr. L. Lewis.

FORESTRY IN BALUCHISTAN

THOSE who have visited Baluchistan, even if such a visit was confined to Quetta only, will know that most of the country, the total area of which is 126,000 square miles, of which 53,000 square miles are under British administration, is mountainous with broad upland valleys and that there is a striking lack of trees and a general absence of vegetation. Barren, sunburnt, rugged hills scored by rocky precipitous gorges, the slopes with scattered dots representing juniper or olive stunted trees, alternate with bare stony plains. Parts of this country, as is the case with the adjacent Seistan and Iran, are fertile enough once water can be brought to them. The rainfall is low, 5–15 in. (the latter in the highlands), but is not so deficient that it could not support, and did once support, a better type of vegetation. Examples are noted of forests having disappeared within the last fifty years, notably around Quetta and near the railway, around Fort Sandeman and Loralai, near Tomagh State Forest, and so forth. It is held that desert conditions are advancing from the west and that these conditions are due to the improvident and unchecked habits and actions of the population—felling, lopping, bark stripping, and excessive and continuous goat browsing, in which the nomads are probably the worst offenders. Erosion is very severe, and one stream which has been under observation is reported as carrying away as much as 450 tons of soil in an hour. Many of these facts have been known for the last three or four decades, but they have never received really serious attention by the administration, and such forest service as there has been has been negligible and of inferior status.

Attention has been directed to the present position of affairs in a "Note on a Tour of Inspection of Baluchistan" by S. H. Howard, acting inspector general of forests (Government of India Press, Simla, 1940), and the report comes none too soon if the remnant of vegetation and the forests in the highlands are to be saved from extermination.

It is a curious reflection on British administration that in so many parts of the world at the present day the similar problem of the man-made desert being brought about by the unchecked acts of the people upsetting to the ordinary laws of Nature is presenting itself to the British administrator.

Juniper (*Juniperus macropoda*, Boiss.) is one of the chief species of the country, and there are remnants of an old forest at Ziarat. The wood of this tree could, says Mr. Howard, be used for pencils, slate frames, picture frames, and so forth, for which a sale might be developed, or a local factory might pay. This presupposes that a greater protection of the forests is introduced by Government and that the Government forest area should be raised from 0.6 per cent of the country (its present extent) to something nearer 20 per cent. Other tree species are olive (*Olea ferruginea*) and khanjak (*Pistacia Khinjuk*). Of these, rough statistics appear to show that a juniper takes 40–180 years to grow one foot in girth (a 6-ft. tree is 250–1000 years old), an olive coppice shoot about 35 years to grow one foot girth, and a khanjak about 25 years. The principal minor product is Ephedra, but Artemisia, Hyoscyamus, Datura, juniper berries and perhaps Pyrethrum are other possibilities. In the highlands one of the chief species is the beautiful chilghoza or silver-barked pine (*Pinus Gerardiana*).

Of course, in so dry a country fuel becomes an important problem. There appears to have been a great development in its supply during the last few years with a corresponding high level of expedition in extraction. This scheme would be disquieting in so barren a country, and Mr. Howard makes recommendations which would certainly appear to be required, that a chief forest officer from the Imperial Forest Service should be appointed, and that the forestry question in Baluchistan should be treated as a question which has become of serious importance if the conditions of life of the population are to be improved instead of the country being permitted to fall into a state of greater desiccation and denudation.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Saturday, March 22

ROYAL PHOTOGRAPHIC SOCIETY (Scientific and Technical Group) (at 16 Princes Gate, London, S.W.7), at 3 p.m.—I. Annual General Meeting; II. "Airscrew", a 16 mm. Sound Film, illustrating Design, Manufacture, Precision, etc.; III. A Demonstration of some Captured German Cameras by a Service Officer.

Tuesday, March 25

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir James Jeans, F.R.S.: "The Physical Condition of the Planets".*

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 3 p.m.—Miss B. Blackwood: "Some Arts and Industries of New Guinea and New Britain" (Films).

Wednesday, March 26

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir Richard Gregory, Bart., F.R.S.: "Discovery and Invention" (Aldred Lecture).

Thursday, March 27

BRITISH PSYCHOLOGICAL SOCIETY (Industrial Section) (at 55 Russell Square, London, W.C.1), at 1.20 p.m.—Dr. Marie Jahoda: "Some Remarks on Incentives to Work".

Friday, March 28

ASSOCIATION OF APPLIED BIOLOGISTS and SOCIETY FOR EXPERIMENTAL BIOLOGY (Joint Meeting at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 12 noon.—Discussion on "The Relationship between Pure and Applied Biology". 12.5 p.m.—Prof. P. A. Buxton: Opening Address. 12.35 p.m.—Prof. W. B. Brierley will speak from the Botanical side. 2.15 p.m.—Dr. V. B. Wigglesworth, F.R.S.: "Malaria and War". 3 p.m.—Dr. M. A. H. Tincker: "Aspects of the Application of Growth Substances to Practice".

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Mr. W. T. Bottomley: "The Economics of the Design of Condenser Plant and Cooling Water Systems, applicable to Power Stations".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PRINCIPAL OF THE LEEDS COLLEGE OF TECHNOLOGY—The Director of Education, Education Department, Calverley Street, Leeds 1 (March 29).

TEACHER OF SPEECH TRAINING in the Aberdeen Education Committee's Schools—The Director of Education, Education Offices, Municipal Buildings, Castle Street, Aberdeen (March 29).

LECTURER IN MECHANICAL ENGINEERING SUBJECTS in the Schools of Technology, Art, and Commerce, Oxford—The Chief Education Officer, City Education Office, 77 George Street, Oxford (April 2).

HEAD OF THE MECHANICAL AND CIVIL ENGINEERING DEPARTMENT of Sunderland Technical College—The Secretary, Technical College, Sunderland (April 5).

ASSISTANT PROFESSOR IN THE DEPARTMENT OF GLASS TECHNOLOGY—The Registrar, The University, Sheffield (April 18).

UNIVERSITY LIBRARIAN—The Registrar, The University, Sheffield (April 18).

PROFESSOR OF ZOOLOGY at Bedford College for Women—The Academic Registrar, Royal Holloway College (University of London), Engefield Green, Surrey (April 21).

ASSISTANT LECTURER IN PHYSIOLOGY—The Secretary, The University, Edmund Street, Birmingham 3 (April 25).

RADIUM OFFICER—The Secretary, Radium Institute, 1 Myrtle Street, Liverpool.

ASSISTANT ENGINEER FOR THE DRAINAGE AND IRRIGATION DEPARTMENT, Malays—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1 (quoting M19316).

SCIENTIFIC UTILIZATION OF RESOURCES AND MAN-POWER

THE Select Committee on National Expenditure has from the start taken a wide view of its functions, as an admirable series of reports testifies. Appointed to examine the current expenditure on the war services "and to report on what, if any, economies consistent with the execution of the policy decided by the Government may be effected therein", with its team of sub-committees, the Committee has constituted itself a body for keeping Government departments up to scratch in many matters which have only an indirect bearing on the war effort. None of the reports yet issued by the Committee more fairly earns the thanks of the nation than the third and fourth reports, recently published, both of which discuss questions of man-power and production. That in its third report the Select Committee should have found it necessary to recapitulate at length the experience in regard to the relation between industrial output and hours of work, is the more disquieting in view of the seriousness of the man-power situation. The warning, it will be recalled, had already been given in a report issued by the Home Office early in the War, on hours of employment of women and young persons in factories, and in a later report prepared by the British Association for Labour Legislation.

The Sub-Committee on Supply Services of the National Committee now reports in fact that the lessons which the War of 1914–18 should have taught seem largely to have been ignored in respect of overtime and hours of work. Even if the demands on man-power had not been accentuated in the present struggle, failure to profit by past experience could not but handicap our efforts. A like failure to learn the lessons of the past is implied in the fourth report of the Select Committee, on contracting. The co-ordinating sub-committee which submitted the report rightly observes that if maximum output is to be achieved the expenditure of national reserves—whether in man-power, in materials, or in capital equipment—must be at a minimum for each unit of output, and one indispensable method of bringing this about is to pay the closest attention to sound methods of contract procedure.

The prime necessity in a war economy is for the maximum and most efficient use of man-power and materials, and from the point of view of the elimination of waste this latest report is probably the most valuable of the eighteen that have so far appeared. Any contract price will contain four elements : the cost of materials, the cost of labour, overhead costs and profit, to which in main contractors' costs must often be added a fifth, payments to sub-contractors. The control of costs is, therefore, the simplest method by which to attain the maximum efficiency. The acute analysis of cost control and departmental organization, and the masterly survey of the conflict between urgency and carefulness in placing contracts, are examples of lucid thinking which should give the report an assured place in the literature of scientific management, carrying implications far beyond its immediate purpose.

The report indeed makes a distinct contribution to the scientific organization of our war effort, on the positive side as well as from the negative aspects of eliminating waste. With the details of this report only a few scientific workers, and chiefly those in administrative positions, are directly concerned. The report recommends a fixed price contract as the best type of contract. When a target is used with a maximum price contract, sufficient inducement should be given to the contractor to effect savings. Closer scrutiny should be given by departments to the costs allowed for labour on costed contracts, with the view of securing that it shall be employed in the most efficient manner, and severe comment on the time lost in doing all over again the costing and inspection work of reliable and experienced firms, and in doing it in several departments, leads to recommendations designed to avoid such waste and to stop duplication of costings by different State departments.

Great importance is attached to the fullest use being made of the capacity of small firms, and to the financing of such firms properly where necessary. The absence of co-ordination of departments is again the subject of severe strictures, although the difficulty of correcting inefficiency or economic defects is recognized. The importance of careful examination of departmental organizations to secure the maximum co-ordination in future planning, to ensure the allocation of labour to the best advantage, and of the effective tackling of the question of training and securing of potential labour, is stressed.

It is significant that the report should have to recommend that all constructional building, with the exception of fortifications and defence works, construction of aerodromes and works overseas, should in future be the responsibility of the Ministry of Works and Buildings. Similarly, the recommendation that the purchase of general stores, clothing and personal equipment should be the function of a separate new branch suggests that the work of allocating duties to the departments best fitted to receive them is not yet complete. The waste, inefficiency and lack of co-ordination brought to light, not for the first time, in this report should not be allowed to persist. It would indeed be deplorable if there were any delay in implementing the findings of this valuable and suggestive report.

As has already been indicated, the third and fourth reports have some ground in common. Looking at the matter from the point of view of economy, the fourth report points out that to meet the demand for speed by heavy overtime is not only costly, but also, as has been shown on many occasions, after a short period of application, causes a high sickness rate and other losses of effort symptomatic of industrial fatigue, and will finally result in an actual decrease in output. The third report deals with this question at greater length, three of its sections dealing with overtime, dilution and training of labour, and with the effect of overtime on costs.

Before the increased drive for production began in May last, the Sub-Committee on Supply Services was perturbed at the amount of overtime which was being worked. Excessive overtime was found to be bad for production, while if a certain amount of overtime was not worked, men left their factories for others where they could earn more by working overtime. These symptoms were intensified as a result of the two months of extreme effort following the Government's appeal after the invasion of Holland and Belgium. Absenteeism became much more common and men arrived late for their work. Sunday labour led to men taking a day off in the middle of the week, when, of course, they only lost an ordinary day's pay. When at the end of July, in the Royal Ordnance factories, where absenteeism had risen to 15 per cent, it was decided to discontinue Sunday labour wherever possible, and very often Saturday afternoon as well, time-keeping improved and production did not suffer, or even increased.

The Sub-Committee accordingly strongly recommends that hours of work should be reduced to those set out in the Ministry of Labour's July circular as soon as possible. It is also essential that any reduction should be generally applied, in order to prevent men moving from one factory to another in search of longer hours and more pay. Only so can adequate account be taken of the four general facts, established during 1914–18, but recapitulated here so firmly and clearly by the Sub-Committee: increased hours of work above an optimum which varies slightly with different industries do not increase output proportionately, and may even result in a decrease; when heavy overtime is worked for prolonged periods, the general health of workers is undermined; if overtime has been prolonged a reduction in hours will increase output, though there will be a time-lag corresponding to recuperation of energy. If general health is undermined, a reduction to optimum hours will fail to effect the required increase of output.

A major cause of industrial fatigue is eyestrain, and the report recommends full and urgent investigation of the interior lighting of factories and workshops. The requirements of the black-out make it essential that methods of lighting scientifically devised to protect the worker from eyestrain should be fully investigated. It is also recommended that the 'spotter' system of roof-watching to avoid loss of production during air-raids should be linked up with the Observer Corps; and that the removal or wiring of glass in the roofs of workshops should be expedited.

The main obstacle to the abolition of excessive overtime is the shortage of labour, especially skilled labour. The remedy for this is dilution and training, and the Sub-Committee considers that there should be a continued drive to attain the maximum dilution of labour. Once more it is urged that the compulsory powers regarding the movement of labour should, if necessary, be fearlessly used. It is particularly desirable that more training should be done in the factories themselves, in addition to the training centres set up by the Ministry of Labour. Moreover, excessive increase in costs is attributed to abnormal overtime increasing costs out of all proportion to the increase in production. The Sub-Committee records its opinion that this situation, in view of experience during 1914–18, should never have been allowed to rise. It accordingly recommends that more attention should be given by the costings department to labour costs, and action taken when they appear to be too high.

The regularity with which examples of failure to profit by past experience occur in these reports is one of their most disquieting features. No less disturbing in its implications is the admission that the Sub-Committee has so far been unable to see the actual costs of scarcely any articles which have been delivered since the War began, so that it has been unable to find out so far whether in its judgment the State is in fact paying too much for its war supplies. Such an admission is more than an indication of inefficient administration and inadequate checks on excessive costs. It amounts to thwarting the prime purpose of Select Committee to watch over expenditure on the war services.

The wide view of its functions which the Committee has displayed in its reports, and the admirable balance of the reports, have won it already an established reputation, and its findings cannot be ignored without danger to the public weal. Even where, as in these latest reports, it makes numerous recommendations in matters of detail, such as constructive suggestions for preventing a break in production and unnecessary use of paper in sending out tenders and drawing up contracts, it is always clear that the wider issues are kept in mind, and that both policy and detail are being sifted by keen, analytical minds, untrammelled by tradition or departmentalism. The warnings conveyed so clearly and firmly in these latest reports are unmistakable. It is for scientific workers, with their fellow citizens, to see that there is no hiatus between this lucid thought and swift decisive action to eliminate the waste and handicaps which inefficient management, departmentalism or impatient but mistaken disregard of past experience, are placing on the development of our resources to their maximum capacity.

AMERICAN VIEWS ON MODERN CULTURE

Science, Philosophy and Religion
A Symposium. Pp. ix+443. (New York: Conference on Science, Philosophy and Religion, 1941.) 1.50 dollars.

THE papers contained in the present volume were prepared for a conference held in New York during September 9–11, 1940, the subject of the conference being "Science, Philosophy and Religion in their Relation to the Democratic Way of Life". Those who initiated the conference maintain that "civilization itself is threatened by the rise of totalitarian systems based on various anti-scientific, anti-philosophic, and anti-religious dogmas". They state—it is perhaps a hope rather than a conviction—that "our common background gives us a broad basis for a united, democratic American way of life". "This way of life must be based ultimately on the religious principle of the Fatherhood of God and the worth and dignity of Man when regarded as a child of God". The conference after its meeting appointed a committee to meet representatives of the Press: this committee overcame the temptations of humility and pronounced the papers submitted to be "contributions of unusual merit to American learning". Further meetings are planned to take place in 1941 and 1942.

In the volume before us there are, including two introductory papers, twenty-four separate contributions. They form a somewhat closely printed and substantial volume. Naturally, they are of varying length—and value. Practically all their authors are associated with American universities, an exception being the French Catholic philosopher, Jacques Maritain. (Throughout this review I shall refer to writers without honorific prefixes: the constant iteration of the title 'Professor' is irritating.)

As one reflects upon the plan of the conference and reads the resulting contributions, two questions of primary importance arise. Is there any vitally intimate relation between some particular political system and the true progress of science, philosophy and religion? Can any unity between these branches of knowledge be made effective at the present time? As regards religion, Christianity was born under a government which, though nominally that of an oligarchy, was in reality a military despotism. Philosophy came to its first maturity in the great days of Greece when Athens was a democracy with, however, a slave basis. It emerged in Christian Europe in the twelfth century when homes of learning, the monasteries, were an integral part of a feudal society. Science began its modern development when the Renaissance, followed by the Reformation, freed and stimulated the minds of men. Some of us would contend from these facts that there is no close connexion between political systems and the growth of true understanding. It is freedom to examine, to speculate, to question all theories and beliefs, which is vital to science. Without freedom of the mind, the philosopher works in chains, and the religious reformer chafes in sullen rebellion. The pluto-democracy which has evolved in the United States is not alone in giving such freedom.

Karl Darrow, of the Bell Telephone Laboratories, writes one of the most valuable contributions to the volume before us. He describes, accurately and not with the allusiveness which is too often a pretentious avoidance of careful thinking, the various revolutions in the fundamental ideas of physics which have taken place during the last half-century. His paper ends with the blunt inquiry: "But what has all this to do with the democratic way of life, or with the contrast between democratic and totalitarian systems"? He answers:

> "So far as the development of physics in particular and science in general is concerned, what it seems to require is a supply of talented people enabled and permitted to go their own ways, so that discovery may occur in whatever logical or capricious or ironical ways may be chosen by destiny. Non-interference is essential. If a government discourages some doctrine of physics because of a fancied clash between it and some political or economic dogma, it is adverse to physics. (Other sciences are more exposed to this danger, but even physics has not been exempt.) If a government impedes the free passage of scientific men or scientific writings to and fro across its frontier, it is adverse to the development of science even within that frontier. If a government denies opportunity to a group which has a great aptitude for science, it is doing harm to science within its own dominion, though some of the harm may be repaired by the benefit to science in other countries from the resulting emigration. If a government extinguishes a class which by breeding and inherited tradition and leisure is devoted to things of the mind, it is doing irrevocable harm to science. Everyone knows that it is mainly in totalitarian states that these things happen."

The quotation is long, but its content is good, sound sense.

The modern world reaches unity in its scientific conclusions. Is any unity possible in the domains of philosophy and religion? The present volume answers that question with an emphatic negative. There is no agreement as to "the religious principle of the Fatherhood of God". There is, moreover, no attempt to reach philosophical or religious unity. Mortimer J. Adler said truly: "The members of this Conference are not co-operatively seeking to agree about the truth, through the painful ordeal of intellectual debate. Each is content to express his own opinions, and to indulge everyone else in the opportunity for similar self-expression". Adler makes a forthright attack on the modern American professor. The latter avoids "what is demanded for fruitful intellectual procedure". "He will not subject himself to the rigours of public disputation". "He is indocile in the sense that, beyond the field of science, he cannot be instructed, because he acknowledges no ignorance". Is it wrong for an English ecclesiastic, remembering the history of the nineteenth century, to read these words with quiet pleasure?

Adler probably intended to expose the weakness of the present volume. It should be, and is not, constructive, a patient attempt to expose differences and to show what measure of unity is possible. Einstein, for example, contributes a brief paper in which he re-affirms the absolute determinism which is his philosophic creed:

> "The more a man is imbued with the ordered regularity of all events, the firmer becomes his conviction that there is no room left by the side of this ordered regularity for causes of a different nature. For him neither the rule of human nor the rule of Divine Will exists as an independent cause of natural events."

So, says Einstein, religious teachers must give up the doctrine of a personal God and "avail themselves of those forces which are capable of cultivating the Good, the True, and the Beautiful in humanity itself". We may challenge Einstein's metaphysics, as we may challenge that of Newton, without denying his greatness. The arguments in favour of his denial that the human will exists as an independent cause of natural events are, it has often been said, overwhelming—apart from the fact that the conclusion is contradicted by our daily experience. If Einstein is right, what are justice, mercy, honour but fancies which please us without affecting the course of events one jot. Whence come "the forces capable of cultivating the Good, the True, and the Beautiful" ? The term 'forces' is doubtless a metaphor, but of what reactions are they aspects? How can the cultivation which Einstein demands have results? Such questions are not missiles in a barren controversy. They raise issues vital to our civilization. The place of moral ideals in naturalism, or in similar creeds which reject a personal God, is not adequately answered by Harry A. Overstreet. Overstreet holds that when "the child-like religionist grows up," he dispenses altogether with the person-like word 'God'. "His religion is mature when he can say : "I believe in love, creator and sustainer of life. To the realization of love-in-life I devote myself". There are too many loose ends in this preaching. What relation has it to the stuff of which the universe is made or, I personally would add, to the mind which gave it form ?

It is perhaps too much to expect a neo-Thomist to join in constructive debate with men for whom his postulated entities are unintelligible. Maritain makes his demands clearly, but the answer, as I see it, can only be a polite 'if you think so, you think so'. In the less skilful hands of Anton C. Pegis, a defence of neo-Thomist philosophy takes the form of an attack on William of Ockham as the empiricist forerunner of the emancipated modern man. It leads up to the assertion that the liberation of the modern man is "a liberation from reason, from universality, from intelligibility, from order and from law".

Such Catholic philosophy is curiously indifferent to critical investigation of the New Testament : and yet the results of such investigation cannot be ignored if the Christian religion is to be integrated into the new cultural unity of the Western world. For this reason it is much to be regretted that in the volume before us there is no attempt to summarize the form which Christian belief must take as a consequence of our new knowledge of Christian origins. William F. Albright's discussion of "Archæology and Religion" is marked by an ultra-conservative bias. Some statements in it, as for example that recent papyri finds refute the idea that certain parts of the New Testament can be as late as A.D. 150, cannot be accepted. A dislike of "modern religious humanism" and the attribution to unspecified opponents of "the rationalistic dogma that all can be explained in terms of mathematics" are not adequate substitutes for a patient re-presentation of the essential principles of Christianity. Donald W. Riddle's "New Testament Study and the Time-Lag" does not supply the need. It is a relatively slight sketch of the history of New Testament critical scholarship. As the author writes of the time-lag, it is worth noting that he does not seem to have known that, when his paper was given, Loisy was already dead.

What has happened to the study of Latin in American universities ? On p. 93, we get *sub speciæ* : on p. 95, *humane laudis amore* : on p. 165, *ignorabinus.* Copernicus would be astonished to find that he wrote a book with the title "De Orbinum coelestium Revolutionibus" ; but Vesalius would be even more surprised to find that he was the author of "De humani corpori fabricia". VICTORIAN TRAVELLER

The Rugged Flanks of Caucasus

By John F. Baddeley. Vol. 1. Pp. xv+272+22 plates. Vol. 2. Pp. ix+318+15 plates. (London : Oxford University Press, 1940.) 126*s*. net.

Mr. John F. Baddeley, the author, died a year ago at the age of eighty-five, just when he had made this book ready for the press. It is the narrative of his travels of some forty years ago.

As a very young man chance took Mr. Baddeley to Imperial Russia, and later on he engaged in business in connexion with the Caspian oil-fields, business which allowed him sufficient leisure to divert himself by riding on horseback for weeks together in and about the northern flanks of the Caucasus. Well versed in Russian, he relied on his servant and guide, an Ossetine, and a man of some standing among his own people, to act as interpreter among the tribesmen, by whom he was received with unfailing hospitality.

There is no doubt that the simplicity of Mr. Baddeley's tastes, his good sportsmanship and generosity, added to his genuine goodwill towards his fellow-men, made it possible for him to achieve an unusual intimacy of contact with the Caucasian villagers. He ate as they ate, slept where they slept, and listened eagerly to gossip, story and song by the fireside. All that he saw he recorded with care, and because these wanderings were among his happiest memories, the old note-books, diaries, photographs and sketches were brought out long afterwards in the days of his retirement and fashioned into a book.

The world Mr. Baddeley pictures is a vanished one, for he never revisited Russia after the War of 1914–18 and the Revolution. Yet he continued to interest himself in the history and literature of the Caucasus, and this travel record is enriched with the musings, memories and studies of the author's later years. He was able, for example, to compare the country as he saw it with the pictures drawn by many earlier travellers, incidentally indicting Klaproth of plagiarism and fraud. The Ossetines, the Galgais, the Khevsours and the Ingooshees were among the peoples visited, and the author has much to say of their legends, folklore, religious observances, manners and customs. He made, too, such notes on ethnology, archaeology, plants and animals as the neighbourhood afforded.

The day has passed, however, when the untrained, unscientific traveller can do more for the scientific investigator than tell him, perhaps, that there is something worth investigating. This is a work to be read for pleasure, the pleasure that can be derived from good English prose, from a finely produced book, and from the companionship of the unassuming young man who rode among the mountains, as well as of the well-read older man who lived among his books. A vice-president of the Georgian Historical Society, Mr. Baddeley was the possessor of a fine library of Georgian history and literature, from which he drew the copious annotations to his earlier travels which add so greatly to the interest of the volumes under review. This collection of books and journals he left to the London Library at his death.

MAKING AND BREAKING ELECTRICAL CIRCUITS

Electrical Contacts
By G. Windred. Pp. xii+403. (London: Macmillan and Co., Ltd., 1940.) 16*s.* net.

A GREAT deal of the results of research on technical problems remains in the form of papers in scientific and technical journals, not always easily accessible. A text-book which brings together the salient features of such specialized work can, therefore, be of great value, but the difficulties in writing such a book are numerous. In the first place, it may date quickly; secondly, a choice must be made as to whether the book is to appeal to those already specialists in the subject, or to those who have only a passing acquaintance with it. In either case the principal value of the book will lie in making a specific contribution to the subject by tying together as many loose ends as possible and getting the whole subject into correct perspective.

The book under review, however, appears to have augmented, rather than diminished, the number of loose ends, and includes some that do not actually exist in the subject. Mostly, too, there is very little real attempt to systematize existing knowledge. One of the reasons for this is that the author has tried to cover much too wide a field; another, that he evidently is very much more at home in practical matters than in theoretical argument. In spite of its defects, however, parts of the book will no doubt find a field of usefulness for students and those who have a general, but not too specialized, interest in the subject.

Chapter i is the only one which deals with contact theory proper. It is an interesting chapter, though here too there seems to be a lack of co-ordination and of completeness. The next two chapters, on joints in electrical conductors and on switch contacts, are purely descriptive and derive very little from the results established in Chapter i. Both these chapters are very uneven, with a tendency to repetition which can scarcely be excused.

Next come two long chapters, headed "Circuit Phenomena" and "Arcs and Discharges". Neither is actually germane and both are inadequate. The chapter on circuit phenomena begins with three pages describing resistance, capacity and inductance, which is surely superfluous in a book to be read by electrical engineers. It then goes on for the next forty pages to give a most elementary account of simple series single-phase circuits, including one or two equally elementary errors. The information offered concerning contacts might have been given in a couple of pages—indeed, it has practically been dealt with in the previous chapter. The chapter on arcs and discharges could only be justified if it were completely up to date and if exhaustive use had been made of this information in later chapters, in which case it should have come earlier. Instead, the treatment is so restricted that little application to contacts or circuit breaker problems can be made. The properties, or even existence, of the arc column (or plasma), which plays such a vital part in high-power circuit breakers, is barely mentioned. Arc suppression is dealt with under two headings—"Suppression Circuits" and "Arc Dispersion". The first is useful, but takes up too much space, while the second contents itself with the description of a few of the principal types of high-power circuit breakers. It is difficult to see why this should have been included. Switch contacts are fully described in a previous chapter (iii), including those used in high-power switches, whereas the subject of circuit breakers proper would require a volume or two to do justice to present knowledge. This part of the book, too, suffers from what might be called a failure to indicate scale. For example, multiple break is certainly advantageous for a certain range of voltage, but is much less so for low or high voltages.

The remainder of the book—two chapters on contact materials and "sliding contacts"—is better, even though the former tends to be somewhat of a catalogue of physical properties. The discussion of the properties required of contact materials might very well have been greatly extended, particularly on such aspects as contact bounce, contact wear and so on.

The indexing could be greatly improved; examples taken at random are "restriking voltage" and "recovery voltage", for which the index is of little help in showing one where to find an explanation of the difference between these terms.

It is to be hoped that in the second edition the author will enlarge the first three and the last two chapters at the expense of the others, and that some attempt will be made to form a logical structure in which the gaps in our present knowledge appear as missing steps and not merely as things one might like to know. At the moment, the book tends too much to the popular science type, namely, a collection of interesting facts arranged under headings, but with no proper background. Perhaps this is partly the fault of the present state of the subject.

Pleasing features of the book are its handy size, clear illustrations and imposing lists of references at the end of each chapter.

A. Morris Cassie.

CHILDREN'S IDEAS OF DEATH

The Child's Discovery of Death

A Study in Child Psychology. By Sylvia Anthony. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvi+231. (London: Kegan Paul and Co., Ltd., 1940.) 11*s.* 6*d.* net.

THIS is an investigation of the idea of death possessed by children of various ages, and of their emotional reaction to this idea. It is partly experimental (using the story-completion technique devised by Prof. Piaget of Geneva) and partly observational. The explanatory principles used are largely those of psycho-analysis, and the inquiry is motivated not merely by academic curiosity but also by the problems of the practical care of children, which are more than usually important at the present time.

The author finds that young children think more about death than is commonly believed, and that they are, in general, less prone to anxiety about it than adults suppose. She does not, therefore, defend the common grown-up desire to protect the child from all perception and thought of dead things or of death. On the other hand, she agrees that it is desirable to avoid stories or expressions of attitudes which tend to give ideas of death a frightening or horrible character. She also agrees with the psycho-analysts that feelings of guilt connected with the death of other people are common in children's fantasies on this subject, and suggests that the adult may help to relieve the morbidity of these feelings of guilt by allowing the child to express feelings of hostility as well as of affection towards those who have died.

In studying the development of ideas of death with advancing intelligence, the author finds a first stage (generally at less than five years of mental age) in which no meaning appears to be given to the word 'dead'. Later (from about six years of mental age onwards) there is clear understanding of the concept with reference to human beings, although it is some years later that reference is made to logical or biological essentials in explaining the meaning of death. The recognition of the inevitability of death in others generally precedes recognition of the inevitability of the child's own death, and this latter may be found an idea too painful for ready admission into consciousness, and ideas of living for ever may be elaborated.

A lasting refusal to allow into consciousness the idea of the reality of death may lead to a disintegration of personality through a perpetual conflict between reality as the child sees it and the reality which is a basis for the society he lives in. Such a refusal may be due to an inborn predisposition to reject unpleasant ideas, but the author is more inclined to the idea that it commonly results from such an emotional experience as the too early loss by death of a loved person which makes the idea of death more than normally painful at the critical stage. In either case the child will need psychotherapeutic help, and the understanding adult may help to avoid a repression of this kind by avoiding a morbid expression of the idea of death by his or her own words and example.

R. H. Thouless.

Chambers's Technical Dictionary

Comprising Terms used in Pure and Applied Science, Medicine, the Chief Manufacturing Industries, Engineering, Construction, the Mechanic Trades. Edited by C. F. Tweney and Dr. L. E. C. Hughes. Pp. viii+960. (London and Edinburgh: W. and R. Chambers, Ltd., 1940.) 15*s.* net.

AN accurate and reasonably comprehensive technical dictionary has become an almost indispensable adjunct to the equipment of the scientific worker, and also to that of the layman who desires to march with the times. The prodigious growth of knowledge in the natural sciences and their applications has, moreover, necessitated the coinage of a multitude of new words, and if a majority of these can be found, alongside the old ones, within the limits of a single volume, much time is saved and efficiency gained. No single technical dictionary can aspire to completeness, but every good one should include the essential words and expressions, and be available at moderate cost.

Judged by the above criteria, "Chambers's Technical Dictionary" comes out very well indeed. It contains an extraordinary amount of condensed information, which, so far as the writer is competent to judge, is both reliable and up to date. Brevity is naturally its soul, and should the specialist complain that excessive condensation must entail slight inaccuracies, his remedy is to consult an encyclopædia and not a dictionary. A minor criticism can be advanced against what appears to be arbitrary classification, for many of the words included in one or other of the 124 categories which the authors have adopted might equally well have been placed in another. Thus there does not seem any special reason why words like 'adsorption', 'aerosol', 'molecule', and 'osmotic pressure' should be termed 'chemical' rather than 'physical'; but classifications are always fallible, and like speculative hypotheses, must be scrapped when they are out of date. Among the few omissions noted is the word 'chemotherapy', and agricultural terms in general, though a number of these occur under 'botany'. On the other hand, the inclusion of a large number of medical terms comes as a welcome surprise.

The success of this book is due to the excellent work of a large team of scientific contributors (whose names are not, for the most part, well known), and to the judgment of the two editors; to them for their ability, and to the publishers for their enterprise, the thanks of the scientific and technical world will be readily given. E. H. T.

Volumetric and Phase Behavior of Hydrocarbons

By Prof. Bruce H. Sage and Prof. William N. Lacey. (Associated with Research Project 37 of the American Petroleum Institute.) Pp. xii+299. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1939.) 28*s.* net.

THIS book is mainly concerned with physicochemical principles affecting petroleum technology. It begins with some mathematical and thermodynamic principles, then deals with one, two, and multi-component systems largely from the experimental point of view, the text being illustrated by many clear diagrams. There are references to recent literature. The phase rule and thermodynamics are really the basis of the treatment, but the correlation of experimental data is what is emphasized throughout. When quantitative knowledge of the physicochemical properties is available it is introduced. The section on multi-component systems should be particularly interesting to the petroleum specialist. An appendix deals with retrograde condensation.

The book is a courageous and successful attempt to introduce the principles of chemical thermodynamics into a region of technical application where they can be of real importance and significance. In recent years much work has been done on the physico-chemical properties of the individual hydrocarbons, and a book of this character will help in pointing out its significance to the technologist.

Chiltern Country

By H. J. Massingham. (The Face of Britain Series.) Pp. viii+120+66 plates. (London: B. T. Batsford, Ltd., 1940.) 8*s.* 6*d.* net.

English Lakeland

By Doreen Wallace. (The Face of Britain Series.) Pp. viii+120+66 plates. (London: B. T. Batsford, Ltd., 1940.) 8*s.* 6*d.* net.

THESE books are the latest additions to the volumes in the series entitled "The Face of Britain". Numerous photographs of the two districts dealt with have been collected, and excellently reproduced. If selection be the criterion of art, almost every one of these photographs is a work of art, for they show both the diligence and the good taste needed for rightly directing the camera, the wide angle of which makes it difficult to exclude inharmonious objects.

Mr. Massingham describes the Chiltern country with a wealth of detail, both in relation to natural features and rural industries (such as chair-making and "bodger" work), which still, fortunately, survive in the beech wood districts. Attractive comments are made on rural architecture, as, for example, in describing the outside chimney of the cottage "reaching its brick stack up from tiled shoulders".

The first chapter of Doreen Wallace's volume on "English Lakeland" is appropriately entitled "Tourists' Paradise". The author writes with more intimate knowledge than that of a tourist, having been born and brought up in the district. The well-informed account of sheep farming on the fells provides a true picture of the relation of life and landscape which is such an important element in the æsthetics of scenery.

With reference to the opinions of the author on the appreciation of Lakeland scenery, there is one point in which we feel bound to record disagreement. We are told, p. 11, that "Wordsworth had the woolly mind of the truly good". His "Guide Through the English Lakes", so far from being evidence of a "woolly mind", is one of the clearest and most accurate analyses of natural scenery that has ever been written.

HENRY E. ARMSTRONG*

By Dr. E. F. Armstrong, F.R.S.

MY father was essentially artistic in temperament and had a fine sensitivity for many forms of art. Thus he had an ear for and enjoyed music, he derived much enjoyment from his black-and-white pictures, and took an interest in modern pottery. He was unable to take a symphony to pieces, to talk of good and bad construction in composition, or to argue about schools of painting; but people who do understand these things are often bores and hypocrites of the first order. A good "companion in music" of his writes: "times out of number I have sat with him on the hardest seats imaginable in order that we should go to three concerts in misery rather than to one in comfort. The dear old man was hypnotized by Wagner and Haydn, Beethoven and Mozart, but could not say why—and thank God for it. Your father's appreciation of the arts was, I think, that of the true Artist: underneath the man who possessed a scientific approach to most things lay the makings of a great Artist."

He had an intense worship for colour either in Nature, on textiles, or elsewhere. Some association of eye effect with the chemical problem of origin gave him a feeling of physical well-being when he viewed a real patch of colour. Some of his happiest days were those spent among the autumn colours, and he wrote with deep feeling about them. His palate was particularly sensitive, especially in later years, to flavour and odour, gifts which led him to find keen enjoyment in fine wines and good food. He never smoked and hated the smell of tobacco except from the best cigars, and in consequence perhaps had a palate of extreme delicacy. In all these matters he was always ready to be educated and acquired much knowledge of the "bitten line" through my collection of etchings, and of wines of virtue through André Simon, greatest and most genial of good companions. It might be said he had a nature abundant in resource which found every moment full of charm. He never let himself be cabined, cribbed, or confined. This wide range of interests often prevented him from completing a piece of work undertaken with enthusiasm, new problems diverting his attention. He set himself a high standard in his writing and would not allow publication until he was satisfied with the final draft.

He definitely lacked the engineer's mentality and the appreciation of what the engineer does. Perhaps for this reason he was never in close association with his colleague, Unwin, and other leaders of engineering. He tried hard to put the ideal of science and the detective method of scientific inquiry before many generations of engineering students at an age when perhaps they were least receptive of aught else but the practical side of engineering, and perhaps in consequence of failure to interest the many became biased against the engineering mentality.

The students of the Chemical Department at the Central Technical College were few in number, but they made up in quality for any lack of quantity. Practically all of them came to the front in their chosen paths; they were forced to do so by the Professor who admonished them when necessary for their own good. In his day he had a greater personal influence on his men both at College and after leaving than any other professor. He was rewarded when at one period his ex-students or staff held so many of the chairs of chemistry; for example, Wynne, Kipping, Pope, Lapworth, Lowry, Forster, Philip, Crompton, and Percival in Great Britain, and Worley in New Zealand, whilst E. M. Rich became chief education officer to the London County Council.

There exists a list of the careers of his old students showing the many branches of industry into which they have penetrated. Most of them have left their mark on their particular industry either by discovery or by rising to high positions in it, and one is inclined to wonder, after studying it, what would have been the position of chemical industry in Great Britain prior to 1914 if Armstrong had chosen the other path at Finsbury and created there a great school of training for the chemical industries.

It is important to emphasize my father's personal interest in his students, both when at college and throughout their careers. He took the greatest pride in their achievements and worked unceasingly for their promotion. Apart from those he actually taught, there were perhaps quite as many chemists who discussed their researches with him and received much help and guidance, often daily letters, coupled with the frankest criticism. Many others, again, came for advice regarding their careers. His enthusiasm for those who accomplished anything knew no bounds and he threw all his influence behind them. One recalls, for example, a shy schoolmaster, H. B. Baker, working on the reactions of dried gases. His brilliant career is well known. My father's correspondence contains a large number of highly appreciative letters from distinguished men, often written on the occasion of their election to the Royal Society.

---

* Part of the first Armstrong Memorial Lecture of the Society of Chemical Industry, delivered on February 3.

Armstrong made a point of knowing everybody in chemistry and as many as he could in other sciences; he specially encouraged the younger men and liked them to make the pilgrimage to his house at Lewisham on Sunday. There are many letters testifying to the influence he had on these afternoons. After tea he used to encourage them to talk about their work, and often late in the evening he would write them some suggestions to overcome their difficulties.

Armstrong had a great capacity for making friends and, what is rarer, of continuing to make new friends in advancing years; they had to be men of independent thought. He had the trait of hero worship in his make-up; all his life he worshipped his teachers Frankland and Kolbe and his friend Dewar, and he had the utmost admiration for many other of his friends; this was particularly brought out in his obituary notices, which were models of graceful feeling. He wrote in reference to Ellwood Hendrick—"A friend cannot be defined. He is never made: he comes, when and how who shall say? Only where the wind listeth. He is the greatest and rarest of discoveries: the inestimable loss." Of such quality was the friendship with Dewar, Messel, W. H. Perkin, senr., the Browns, Horace and Adrian.

My father always felt he owed much to the very remarkable scientific quartette at Burton-on-Trent—Peter Griess, Cornelius O'Sullivan and the Browns—all active in the scientific service of brewing. The achievements and influence of these four men on chemical science have been profound. Armstrong has done full justice to it—"They sought neither gain nor applause; love of their art was their guiding light; they were led solely by desire to explore its fields, to grasp its value, to display its beauties."

He frequently went to Burton and corresponded closely with his friends; the introduction to brewing gave him a life interest in this subject, with which he maintained close contact all his life. He pleased to be a good-humoured critic of the quality both of the product and of the science put into it on diverse occasions, and had many friends in the industry. I myself was at one time destined for Burton, but Fate turned my path to biscuits instead of beer.

As a young man my father was extremely earnest and unsociable; my mother had the greatest difficulty in getting him to go anywhere; he paid only a very few calls on Sunday mornings to old family friends. His whole life was devoted to his work at the College, to teaching and research and to affairs of the Chemical Society. When he came home he wrote letters until late into the night. It was much later in life that he allowed the latent social side to develop, when he had leisure to go about and meet people.

My father shone also as a host; the formal dinner parties at Lewisham were in the true Victorian style, with Clarke, the laboratory attendant, called in as a waiter. The guests were most carefully paired and many interesting people came to the house. One such party included Sir George Robertson, the hero of Chitral, and Prince Kropotkin, then a prominent Russian revolutionary, though to-day his politics would be considered the palest of pink. We had no cellar book like Saintsbury, but a visitors' book was maintained from 1894 and in time it became an honour to be included in it. It is truly international; every American or German chemist who came to London made the journey to Granville Park, generally on a Sunday, and the names of few of the British chemists of the day are missing. A frequent entry is that of Joji Sakurai. His is the last name in the book; he called on May 21, 1937, when my father was confined to his room. My sister tells me that at 3 o'clock in the afternoon a half bottle of champagne was sent for so that the two old gentlemen might drink to one another. Sakurai passed away on January 28, 1939.

In his later years Armstrong became the guest *par excellence*. Adorned with his coloured waistcoats, his one personal vanity, though he claimed them as an advertisement for the achievements of the dye industry, he became a much-sought table companion at the dinners of the Omar Khayyam Club, the Saintsbury Club, the Wine and Food Society and many similar occasions; he enjoyed also the banquets of the London Livery Companies. His knowledge was so wide, his range of subjects so varied, his views so original and outspoken that they aroused the interest of his table companions. Very often correspondence and friendships followed these chance meetings.

One dining club merits special mention, namely, the original Chemical Club, which was an exclusive body, limited to forty chemists elected by ballot; it met monthly on the same days as the Chemical Society. Formed in November, 1872, the first secretary was Pedler, but Armstrong took on the task in the following February and continued to perform it for many years until the constitution changed and the dining club became associated with the Council of the Society. The history of most dining clubs is much the same. They either become too formal and dull and so lapse, or they depend on the enthusiasm of one man and a set of regular participants. The old Chemical Club took the latter path; it became entirely informal, minutes, rules and subscriptions were in abeyance and it relied on Armstrong, or rather Mrs. Armstrong, to send out the monthly cards and order the dinners. Here the older men were met on level terms by the younger, and many enduring friendships were formed. Here also it was possible to entertain appropriately distinguished foreign visitors to our shores.

My father took delight also, when the Chemical Dining Club was no more, in arranging dinners at the Athenæum and elsewhere to distinguished visitors to London, when representative Londoners widely chosen were gathered to meet them.

The successor to the Chemical Club has been the Catalysts, now also a mature body. Armstrong was seldom absent from these dinners and did much to make them enjoyable. He was a regular chairman also at the monthly lunch meetings of the Old Centralians, a gathering which gave him lively satisfaction.

> "He that enlarges his curiosity after the works of nature demonstrably multiplies the inlets to happiness."—Johnson, Rambler No. 5.

Academic life gave my father full opportunity for holidays, and he enjoyed the absence from London. He enjoyed walking and continued it into the 'eighties and would have no other sport. I remember Lockyer trying to get him to take up golf on Blackheath. A regular Sunday morning walk across Blackheath to the Observatory in Greenwich Park will always be associated by me with his memory.

In his early youth he walked a good deal in Scotland; later he went abroad to Switzerland and Norway, then just opening up for tourists, often in company with Tilden or Clowes.

For the family holidays which played so large a part in his life, Margate was at first the chosen place. Here he had Lauder-Brunton and Hardy, the eye specialist, among others, to see; Lockyer was at Westgate. In later years the geological general practitioner Dr. Arthur Rowe was his great friend there. We were taught at an early age to walk; to study the changes in the soft chalk, in that district very rapid; to look for fossils; to visit churches and to learn the history of the Roman occupation and of the Cinque Ports.

Beginning about 1886, Lyme Regis was chosen for Easter. The Tildens came too, also Wynne; Lord Lister lived at the top of the hill. By that time we youngsters could walk farther, but even so the ascent of Golden Cap was a feat, and more than one visitor found the two miles or more of shingle along the face of the intervening hill enough for that holiday.

A visit of the Geologists' Association took us to Swanage one Easter (1895) and there and then the cottage on the pier was secured for the summer and for many future holidays. Here the family was trained in nature study—to collect, to observe, to record as part of a normal enjoyable holiday. One of his children should have become a biologist, nurtured under such environment, but heredity or some other factor proved too much for us and we have remained normal people taking perhaps a special interest in our holidays and collecting as a hobby. The Isle of Purbeck is still a unique centre for study with three geological ages in juxtaposition, involving three different flora and fauna. My father gave much time to his coastal photography here; it involved carrying around a heavy camera, tripod and glass plates, and sundry adventures by way of trespass or in boats to secure pictures of selected sections.

We had the ambition to walk round the English coast on the coastguards' path and in course of time accomplished all the worth-while sections, writing up the experiences in the form of illustrated and annotated log books. We were induced in this way to look up the history or other information relating to places and objects, and so learnt at an early age how to consult books of reference and make a précis of information. This training was of the utmost value; it helped to teach us to learn easily anything which appeared of interest, though we were as stubborn as other children in refusing to learn the dull stuff taught at school. None of us was high in class except in our pet subjects which we mastered with ease.

The transference of affection to the Lake District came later, the introduction being effected on a Geologists' Association trip led by Marr. Here Armstrong had his happiest days and he returned to Manesty Farm near Grange, with its unique views into the jaws of Borrowdale in the one direction and across Derwentwater to Skiddaw and Saddleback in the other, as often as possible each year for many years. Long walks were carefully chosen to give variety and interest, and formed a programme of increasing severity to suit all weather conditions. Some of the most arduous gave him greatest joy; the long grind round to the top of Grasmoor, the attack on Gable from Green Gable via the side of the slate quarry on Honister, the walk up Ennerdale and the climb out at the head of the valley, the ascent from Seathwaite to below Great End and the climb up Cust Gulley were some of his favourites. Another was the ridge walk to Causey Pike followed by an abrupt descent that often caused havoc to his companions, in which he took secret delight. The use of a car to lessen road distances and make new walks possible in later years added greatly to his enjoyment.

He loved having visitors at Manesty, and very many came there; he would talk freely on the hills and in the sitting room on slack or wet days and gave mental stimulus, as only he knew how, to not a few. He made friends with the parson, Canon Rawnsley, at Keswick, and took an active part in all the fights to preserve the Lake District against vandalism. The greatest joys of all to him were the days when the snow came and gave yet one more touch to the kaleidoscope of colour on rock and hillside. Those who knew him in the hills perhaps saw him at his best and most versatile —a philosopher, wise in very varied knowledge, more full of zeal than tolerance, perhaps, putting the cause above worldly ambition.

Armstrong was strongly individualistic and gloried in being so; in his later years he enjoyed being provocative and exaggerated his attacks—in his own words—"there is more fun in laying about you." As a freelance without occupation he had not often the opportunity to be constructive. In a wiser age perhaps his abilities would have been more utilized.

It must be remembered that he was the product of an age when transport was slow and communication limited—the horse and buggy days of our American cousins. Whereas there were then many small local worlds, to-day there is only one large world in which the radio brings an event to the notice of everyone within a few seconds of its happening. Science and philosophy to-day more than ever seek to submerge the particular in the universal; there is little room for the unique individual, who is looked on as irrational. The desire of the human mind is for unification; all that is, was, or ever shall be, originates from one source. Most students to-day accept this view as a doctrine of scientific faith and regard one who combats it as outside reason. Hence perhaps the failure of the youngest generation to appreciate Armstrong's greatness. Had he lived fifty years earlier he would have been venerated for the very reason that he had been criticized. Hence the fact that his outpourings in scientific journals were most appreciated by older men and in the United States, which is still largely individualistic.

As an adventurer Armstrong could not understand the satisfaction to be gained from committees and conferences. Immediate action appealed to him; the need of the cause was too urgent to allow time in which to placate the opposition. It has been said that disapproval occupies the greater part of our conversation; it is tempting to say how a job ought to be done when one is denied the opportunity to do it.

Progress, educational or otherwise, means hard fighting not for one lifetime only but for generations. Those whom Priestley termed "the men who will never learn" are strong. Meredith's simile of the hair, in that remarkable work the "The Shaving of Shagpat", as illustrative of the errors, injustices, or illusions which an enormous effort is required to destroy, appealed very much to my father. His ideals were those for which we are fighting to-day. To him they were clear and patent. In an address in 1935 to the Frankland Lancastrian Society he wrote, "as human beings most of us are only interested in ourselves. | We have to learn without delay how much more we might, could, and should do for ourselves." He outlined some of the immediate needs of the nation and emphasized how the inquiry will demand an extraordinary use of intelligence which in large measure will have to be developed for the purpose. We are trying to do these very things in 1940–41, under difficulties of which "the hair" is the greatest.

My father was a great reader. Probably no one knew the chemical literature up to a certain period better than he did and he possessed a most retentive memory. In later years with more leisure he read very widely. He appreciated that "the worth of reading is in its after effects; it forces big thoughts and compels the recognition of new aspects of common things." His writings are full of quotations, Lewis Carroll being one of his favourite authors for this purpose.

He mentions the influence of Trench's book "The Study of Words" on his youthful impressions and his then habit of omnivorous reading. He gladly returned to this when he gave up his professorship. The influence of good companions is to be found in his later writings, which were often brilliant apart from their pungency.

Some words of Lafcadio Hearn are, I think, appropriate to him, namely, that if a man has a very powerful imagination as well as a very large sympathy the study of science alone will give him everything he needs. "He can get the water of emotion out of any desert of dry facts." Hearn says that such men are very rare, and students of science, who normally tend to be hard, are counselled to read emotional literature. I think it will be agreed that his addresses of later years are full of feeling; he took enormous pains with them.

My father had a wonderful old age; he found something to do every day, kind friends to encourage him and though his hearing began to fail, his vitality and mental energy were unabated. Only on the death of his wife in the last days of 1935 did ill-health overtake him. He bore a long period in his room with great patience and preserved his mental faculties to within a week of his passing on.

He accepted the creed of Ben Ezra, who so boldly declares that old age is better than youth simply because of its being the time of knowledge and understanding.

He has marked Browning's verse :

> "Thoughts hardly to be packed
> Into a narrow act,
> Fancies that broke through language and escaped
> All I could never be
> All men ignored in me
> This I was worth to God, whose wheel the pitcher shaped."

He hoped much from heredity and believed the best qualities of a man may appear in his grandchildren or great grandchildren ; they furnish the proof of the worth of the ancestor, using the words of Lafcadio Hearn. The tragic death of his grandson, Kenneth Frankland Armstrong, in whose career H. E. A. took so much pride, was perhaps the greatest blow of his life.

I have sought to trace the life-history of a versatile, individualistic man ; one who kept himself fit in body and also in mind ; one who gave unstintingly of his best to many causes without thought of fame or honour for himself ; it was indeed his nature to decline all such. If the task has been achieved we have seen what is so well expressed in the words of Walt Whitman :

> "Journeyers gaily with their own youth,
> Journeyers with their bearded and well-grained manhood,
> Journeyers with their own sublime old age :
> Old age, calm expanded, broad with the haughty breadth of the universe."

'WORKING-CLASS' EARNINGS AND EXPENDITURE

BY D. CARADOG JONES,
SCHOOL OF SOCIAL SCIENCES AND ADMINISTRATION, UNIVERSITY OF LIVERPOOL

DEFINITION OF 'COST OF LIVING'

THE nominal wages of a working man are in the main governed by the demand for and the supply of such skill as he possesses. His real wages—what he can buy with his money—depend upon the movement of prices. During a war, the mounting cost of living invariably directs public attention to the need for regulating wages so that real and nominal shall keep step. The 'Cost of Living' Index was designed for this purpose in 1914 and has been widely used ever since.

'Living' clearly has a very different meaning in different social circles, so that changes in the cost of living of different classes cannot be accurately measured with the same instrument. Agreement must accordingly be reached upon a standard, a definition of living, if we are to measure its changing cost. The purpose of the Ministry of Labour Index is to measure the average increase in the cost of maintaining unchanged a standard of living of the working-classes as defined in 1914. Strictly, therefore, this index is a measure of price changes—the mean change in price of an aggregate of certain specified commodities the enjoyment of which constitutes 'living'. The choice of these commodities was based on an analysis of 1944 urban working-class family budgets collected by the Board of Trade in 1904, but between 1904 and 1914 the Sumner Cost of Living Committee (1918) reported that "no considerable changes took place in the mode or standard of living". These budgets indicated that, in spite of a wide divergence in expenditure between families, certain needs are common to them all. These basic needs alone, things which from time to time practically every family buys, are used to define living. The number included in the 1914 calculations was severely limited ; the list of foods, for example, contained only fourteen commodities : no fruit and no vegetables, except potatoes, were included. In such respects the standard of living of the working-classes has risen considerably since the War of 1914–18 ; to this improvement the cultivation of allotments, advance in the science of preserving and storing food, quicker transport from abroad have all contributed. Consequently, an analysis of household budgets to-day reveals a marked extension of the field of basic expenditure.

NEW COLLECTION OF HOUSEHOLD BUDGETS

The first results of the recent and most elaborate budget inquiry ever undertaken in Great Britain by a Government department were published in the *Ministry of Labour Gazette*, December 1940. The households invited to keep budgets—and encouraged to do so by a small payment for each approved budget—were determined by a purely random choice of names from the registers of adult workers insured against unemployment, all districts throughout the United Kingdom being adequately represented. Certain important classes of non-insured workers were also included, but applicants for unemployment assistance (that is, long-standing cases of unemployment) were excluded. With this reservation the households represented may be described as those of manual workers, and non-manual earners of salaries up to £5 a week engaged in industrial, commercial or clerical occupations. Agricultural workers do not concern us in this article. In Great Britain alone, 31,000 households were visited; about 9,000 proved to be outside the scope of the inquiry or were ruled out for some other good reason; of the remainder, nearly 60 per cent co-operated. So high a return in this type of investigation exceeded expectations. It reflects great credit on the Statistical Division of the Ministry of Labour directing it, on the employment exchanges and advisory committees throughout the country, and on the thousands of voluntary workers who formed the direct link with the families visited. The majority of these families kept a satisfactory record of expenditure for four specified weeks, in October 1937, and in January, April, and July, 1938. We may confine our attention to these 8905 households, since the addition of budgets kept for a shorter period makes no significant difference in the figures.

MEAN SIZE OF HOUSEHOLD AND ACCOMMODATION

The information so far available from these new budgets is best summarized in the form of averages. Thus, the average budget family was composed of 3¾ persons, including 2½ adults over eighteen years of age and one child under fourteen. Two persons per family were dependants and the earners worked on the average five days a week. Two per cent of the families—mostly miners—lived rent free in dwellings provided by their employers; nearly 18 per cent either owned or were buying their houses; the remaining 80 per cent paid rent and the mean number of rooms occupied was 3·9. The average weekly rent (including rates and cost of purchase when relevant) was 10*s*. 10*d*.

EXPENDITURE

The average weekly expenditure per family on food was 34*s*. 1*d*. Of this, 10*s*. was allocated to meat (including bacon, fish, etc.), 9*s*. to dairy produce, 5*s*. to bread, flour and cakes. The mean consumption of meat and bacon per family was nearly 6 lb. each week, of butter and margarine 2½ lb., of sugar 4¾ lb., of eggs two a day. The average consumption of bread and of potatoes by each person was just over ½ lb. a day, while that of milk was appreciably less than ½ pint a day. The change in distribution of expenditure as compared with 1914 and the trend towards middle-class expenditure, as revealed in the accompanying table, is of particular interest.

PROPORTIONAL DISTRIBUTION OF EXPENDITURE ON FOOD.

Expenditure on	Working-class budgets		A middle-class sample
	1914* %	1937–1938 %	1926* %
Meat, fish, etc.	32·0	31·2	37·5
Bread, flour, cakes	19·3	15·7	12·2
Dairy produce	22·3	27·9	25·9
Vegetables, fruit	9·7	13·3	13·2
Sugar, jam	7·5	5·1	5·1
Tea, coffee, cocoa	6·6	5·8	4·6
Oatmeal, rice, etc.	2·5	1·0	1·5

* Derived from an article by D. Caradog Jones (*J. Roy. Statistical Soc.*, 91, Pt. 4, Table xiii).

The weekly consumption of coal amounted on the average to 1¾ cwt. for each family, the expenditure on fuel and light together being 6*s*. 5*d*. a week. Out of the 8905 households who kept satisfactory budgets of their total expenditure for four weeks, 2100 were persuaded to keep a detailed record of what they spent on clothing and footwear for twelve months. On this additional and more reliable evidence the total average expenditure on clothing is estimated at 8*s*. 1*d*. a week per family.

DISTRIBUTION OF TOTAL EXPENDITURE.

Expenditure on	Working class			A middle-class sample
	1937–38	1914*	1937–38	1926*
(1)	(2)	(3)	(4)	(5)
	s. d.	%	%	%
Food	34 1	60	40	32
Rent and rates	10 10	16	13	14½
Clothing	8 1	12	9½	11
Fuel and light	6 5	8	7½	4½
Miscellaneous	25 7	4	30	38
Total	85 0	100	100	100

* *J. Roy. Statistical Soc.*, 91, Pt. 4, Table xii.

Acting on the principle of including in the calculation of the Cost of Living Index only basic needs, the Ministry of Labour has hitherto given very small weight to expenditure on items other than the four main groups already considered. Their miscellaneous group included only such cleaning materials as soap and soda; domestic ironmongery, brushware and pottery; tobacco and cigarettes; fares; and newspapers. These items between them account in the new budgets for an expenditure of 7*s*. 4*d*. a week on the average. But in addition, these budgets include compulsory national insurance, costing 2*s*. 1*d*. per family, while voluntary insurance premiums and trade union subscriptions together amount to 3*s*. 9*d*., whereas the total average expenditure on all items in the miscellaneous group is 25*s.* 7*d.* The difference is made up of house furnishings (2*s.* 7*d.*), entertainment (1*s.* 4½*d.*), hospital, medical and dental charges (1*s.* 8*d.*) and other expenses.

The ultimate result of this analysis of present-day expenditure is summarized in columns 2 and 4 of the accompanying table, and again comparison is made with working-class expenditure in 1914 and middle-class expenditure in 1926, bringing out as before the closer approach of the working-class towards the middle-class type of distribution.

EFFECT OF NEW WEIGHTING ON COST OF LIVING INDEX

What difference would the use of the new weights shown in column 4 above make in the Cost of Living Index ? To answer this question we must understand precisely what it means. Suppose we wish to compare costs at two given dates, July 1914 and the period 1937–38 to which the new budgets relate. The index at present in use measures the increase in the cost of maintaining unchanged the 1914 standard of living as already defined. There is only one correct way of doing this, and the answer is given month by month in the *Ministry of Labour Gazette.* If we calculate the mean of the official price indexes at the four dates nearest to the budget weeks, we find that food had risen 42 per cent, rent and rates 59½, clothing 110, fuel and light 80½, and the miscellaneous group 75 per cent between July 1914 and 1937–38. Each of these percentages, *by definition,* must be weighted according to its importance as judged by the average proportional expenditure upon the corresponding group in July 1914. In other words, the appropriate weights are those given in column 3 of the accompanying table. This leads to the conclusion that the cost in 1937–38 of 'living' as defined in 1914, was 57 per cent above the 1914 level.

But suppose we change our standard and proceed to compare with this figure the 1914 cost of buying the commodities which constituted 'living' as defined by the average of the 1937–38 budgets. We start now with the distribution of expenditure shown in columns 2 and 4 of the table. To find the cost of this average budget in July 1914 we must allow for the mean change in price of each of the five groups between 1914 and 1937–38 given above. This done, we find that the budget which cost 85*s.* in 1937–38 would have cost only 52*s.* 9*d.* in 1914. In other words, the average budget of 1937–38 cost 61 per cent more at that period than it would have cost in July 1914. If, therefore, we wish to define 'living' according to the present-day standard in place of that of 1914, the result will be a rise in the 'cost of living' from 100 to 161 instead of 100 to 157. It may be presumed that this difference is much less than the critics of the old Cost of Living Index anticipated. It illustrates the validity of the statistical principle that the weighting of price movements—normally based on a selected standard of living—is of less importance than the price movements themselves, which are independent of the particular standard selected and determined afresh each month.

RELATION OF EARNINGS TO EXPENDITURE

One further question of interest remains. How is the average standard of living, represented by these budgets, related to the present-day level of earnings ? To answer this question use can be made of data given in the November and December issues of the *Ministry of Labour Gazette* 1940, concerning average earnings in the principal industries at July 1940. Agriculture and mining are two notable omissions from the industries listed, but it is reasonable to omit them as we are only concerned with urban budgets. It will be appropriate also to confine our attention to men's earnings in dealing with household expenditure ; and in order to obtain a composite average it will suffice to weight the earnings in different industries by the number of occupied males, aged 14+ , in each as given by the 1931 Census for England and Wales. The resulting average of weekly earnings is 87*s.* It should be added that under war conditions two industrial groups, by reason of the numbers employed, have a predominating influence in producing this result, namely, the metal, engineering, and shipbuilding group and the transport and storage group. Another point to be noted is that average wage rates would, of course, be at a distinctly lower level. We have also information, in the same two issues of the *Labour Gazette,* as to the percentage increase in men's average earnings for each of the same industries since October 1938, a date more closely approximating to the budgets period. By weighting these as before it may be estimated in round numbers that average earnings in October 1938, for these combined industrial groups, were in the neighbourhood of 70*s.* a week. Bearing in mind that on the average there were 1·75 earners per household, this would give an ample margin to meet a weekly family expenditure of 85*s.*, even allowing for the probability that all earnings do not go towards housekeeping.

Averages, useful as they are, do not bring out the light and shadow in the picture. If we could be also told what the budgets reveal as to range of spending, we should have fairly accurate and unique information as to the relative poverty and wealth of a large section of the population.

THE BANANA IN CENTRAL AMERICA

III. PANAMA DISEASE

BY PROF. C. W. WARDLAW,
UNIVERSITY OF MANCHESTER

DURING recent years in Jamaica and Central America, the spread and intensification of leaf disease of bananas, *Cercospora musæ*, Zimm., has tended to deflect public attention from another epidemic disease of long standing and of great economic importance, namely, Panama or wilt disease, caused by the soil-borne fungus, *Fusarium oxysporum cubense*. To-day the question is often asked as to which of the two diseases presents the greater danger to the industry. During 1935–40, an observer, surveying the almost incredible damage wrought by leaf disease in such a brief space of time, and aware of the much slower spread of wilt disease, might well have been tempted to regard the former as the greater evil, assuming that he did not take refuge, as Sir Roger de Coverley almost certainly would have done in the circumstances, in the view that there was much to be said on both sides. Among the more enlightened members of the planting community, however, the opinion is held that wilt disease is the more serious problem since leaf disease can be, and is being, controlled, whereas wilt disease can not. From the investigational point of view, leaf disease, while not a simple problem, nevertheless is not beset with those complications which are inseparable from the activities of soil pathogens, and whereas it is known that bananas resistant to wilt disease can be obtained by hybridization, the work is slow because of technical difficulties. So far, indeed, no hybrid has been obtained which possesses the many qualities which have made the Gros Michel the commercial banana *par excellence*. Moreover, it is apparent that some considerable time must elapse before such a hybrid is produced. In some respects, therefore, the Panama disease situation remains very much what it has been for many years. The disease, of course, has continued to spread and has led to the discontinuation of banana growing in many areas.

The passage of time has not lessened the many curious and unexplained aspects of Panama disease. Some instances may be cited. Perhaps one of the most surprising situations is to be found on the lower Ullua River in the Republic of Honduras, where, notwithstanding periodic inundations by flood water carrying debris from affected areas higher up, large areas have remained in a high state of production, with a negligible amount of wilt disease, for a period assessed at fifty years. By contrast, areas inland from La Ceiba have been seriously affected by disease within two years of planting. There, the evidence is suggestive of a pre-cultivation dispersal of the pathogen during the periodic flooding of the forests adjacent to the river, wilt disease having been observed in areas scoured by the flood water higher up. On being planted with bananas, such areas have rapidly gone out with disease. Many instances are known of the 'resistance' of older areas and the 'susceptibility' of new. Whether conditions on the floor of virgin forests are specially favourable for the propagation and distribution of *F. cubense* has not, so far as I am aware, been investigated in detail, but the evidence strongly suggests that they are.

A particularly obscure problem is presented in certain areas which for many years have appeared to possess 'resistance' to the disease but which suddenly begin to be seriously affected. Dispersal of the pathogen by flood water is not involved, and so far the nature of the factor which is operative has not been ascertained. An increase in the pathogen population doubtless bears a direct relation to the increasing incidence of the disease, but relevant data are scanty or absent.

On the controversial question as to whether fresh outbreaks are principally due to contact with neighbouring diseased plants or are the result of new sporadic infections, little can be added save that numerous instances of both abound in those areas where the disease is making headway. It has been observed that spread by contact takes place more rapidly in some soils than in others: the more open the texture and the more acid the soil, the more rapid is the spread of disease. Alternatively, clay soils and slightly alkaline soils appear to possess more 'resistance' to the disease. This information has now been available for some years[1], and recent observations would seem to bear it out. On light riverside soils, for example, the spread of disease from foci of infection may be particularly rapid. Recent years have also shown that clay soils, for many years considered 'resistant', have eventually shown an even more rapid spread—a phenomenon for which no adequate explanation has so far been forthcoming. Other areas are also known which, after many years in an almost disease-free state, are now becoming rapidly affected. The collective experience, practical and scientific, in Central America is that hydrogen ion concentration is the master factor determining the severity of Panama disease, followed by texture; but, as Reinking's work shows, distribution of the pathogen and density of its population in the soil obviously require careful consideration[2].

The Panama disease situation in Central America is being closely watched, and on the properties of the larger companies every effort is being made to check its spread and to test out any new idea which might eventually have some economic value. An unusually interesting and important experiment is in progress at the present time. This consists in flood-fallowing an area of about a hundred acres which had previously been put out of production by Panama disease. The area has been empoldered and divided into four sections, each to be kept submerged for a different period of time. The maximum period of inundation will be eighteen months. This experiment is based on the facts that soil fungi such as *Fusarium cubense* require oxygen to live, and that, when highly infected soil was submerged for one month under two feet of water, no *F. cubense* could be found in it. The outcome of this experiment will be awaited with the greatest interest by all associated with the extensive alluvial banana lands of Central America. Already it has been found that in new land, built up by the sedimentation of controlled flood water, and therefore subjected to several inundations, the incidence of Panama disease has been negligible. This may be considered as an indication of the probable success of flood-fallowing, but time alone will tell. A successful result will obviously have an important bearing on the whole question of banana production in the Caribbean.

OBITUARIES

Prof. G. Dawes Hicks, F.B.A.

THE loss of Prof. G. Dawes Hicks, on February 16, at the age of seventy-eight, will be felt, not only by the wide circle of his personal acquaintance, but also by all who have at heart the interest of philosophy in Great Britain. Friends and students will cherish the memory of his kindly and affectionate nature, his simplicity of heart, his unfailing courtesy, the generous hospitality of his house and table, and his readiness to place his store of learning and the rich resources of his library at the disposal of all students of the problems that engrossed his life. They will not easily forget the short spare figure of the teacher whose frail appearance veiled an iron constitution, that enabled him to excel as a climber and to carry out the duties of his London chair from his house in Cambridge with unabated efficiency. He was professor of philosophy in University College, London, during 1904–28, and lectured on psychology at Cambridge regularly. His energy both of body and mind was amazing. Even when stricken with illness and the sorrow of his wife's death his high courage never failed him; in his last three years he published his Hibbert Lectures on the "Philosophical Basis of Theism" and a volume of noteworthy essays, and persisted in his work as sub-editor of the *Hibbert Journal* from his sick-bed to the very end. He had been largely responsible for founding the *Journal* in 1901–2.

Hicks loved philosophical discussion, whether by his own fireside or at public gatherings, such as those of the Aristotelian Society and the Mind Association. He was secretary of the Aristotelian Society for many years, and its president in 1913. When he spoke it was with lucidity and precision, voicing definite convictions uncompromisingly but with singular modesty. No one could fail to be impressed by his fairness in controversy, his intellectual integrity, and the distinction of mind that lay behind his quiet measured utterances. It was the same with his writings. Disdaining all artifices of style or appeals for popularity, he wrote as a philosopher for fellow-philosophers, so that his books were scarcely calculated to rouse attention outside the academic boundary. They were caviare to the general; though his study of Berkeley, in the "Leaders of Philosophy" series, forms the best introduction to that thinker in the language, and the addresses delivered annually as a labour of love at the Carmarthen College, published in 1928 under the title "Ways towards the Spiritual Life", have a charm that goes straight to the reader's heart. It can truly be said of him that he wrote nothing that does not repay the reading.

Hicks was before all things a critical thinker, in the true Kantian sense; throughout his life he kept himself pure from the extremes either of scepticism or of dogmatism. He was very learned, recalling in his chosen way of life the *Gelehrter* of a now almost forgotten Germany rather than the normal type (if such there be) of an English university professor. But for all his scholarship he remained master of his own mind, and his thought was always on the move. To the end he was faithful to the example of his first great teacher, Robert Adamson. His studies at

Oxford and in Germany led him by way of Neo-Kantism to an idealist position akin to that of Bradley, and thence to the *via media* on which he took a firm stand during the last twenty years of his life, and to which he gave the appropriate name of 'Critical Realism'. The problems that most engaged his mind were in the fields of theory of knowledge and the philosophy of religion. His realism, evidenced in the refusal to allow any "bifurcation of Nature", was, in many respects, akin to that of Whitehead. Why, he kept asking, should not the grass be really green? He contended resolutely against the naturalistic fallacy of treating the knowing subject as an object among other objects. Perhaps his most characteristic doctrine was the threefold distinction that he discerned, alike in perceptual and conceptual thinking, between the activity of apprehension, the content apprehended, and the apprehended object; a distinction by which he endeavoured, in a manner reminiscent of the scholastic distinction of the *id quod concipitur* (the object) from the *id quo concipitur* (the concept), to escape both the Scylla of naïve realism and the Charybdis of representative perception.

In religion Hicks was all his life a member of the Unitarian communion, in which he had in earlier years exercised the ministry, from 1897 until 1903, at Unity Church, Islington. In his Hibbert Lectures he set himself to expound the rational grounds for his strong theistic faith. The strength of the book lies in its massive presentation of the cosmological, teleological, and moral arguments as a correlated sequence of evidence to a God, who is at once distinguishable from the Absolute of monistic idealism and subject, on epistemological grounds to temporal succession. The weakness lies in the author's evident lack of sympathy with any form of mysticism and in his disparagement of the evidence from religious experience. The thought of man's relation to God as that of a subject to a *subject* seems scarcely to have crossed his mind.

That Hicks left no finished system of philosophy was doubtless due in part to his lack of speculative imagination. He cannot be ranked with thinkers like Bradley, Alexander or Dr. Whitehead. But he threw much light—a dry light, as befits a philosopher —on many of the most important problems of modern thought. In early days, for example, he had studied psychology and psycho-physics under Wundt, Heinze, Volkelt and Hering, an interest that was fortified and deepened later through his friendship with James Ward. A striking essay on "The Dynamic Aspect of Nature" and another in criticism of Sir Arthur Eddington testify to his grasp of recent developments in physics. He gradually came to be recognized as one of the most competent and judicious thinkers of his generation; his old University of Manchester conferred on him a doctorate, and in 1927 he was elected a fellow of the British Academy. He will be long remembered with honour as a great scholar and teacher, a disinterested inquirer after speculative truth, and one of the most lovable of men.

W. G. de Burgh.

Prof. C. R. Lanman

We regret to record the death of Prof. C. R. Lanman, the distinguished authority on the ancient languages and culture of India, emeritus professor of Sanskrit in Harvard University, which took place at Boston on February 20 at the age of ninety.

Charles Rockwell Lanman was born at Norwich, Connecticut, on July 8, 1850. He graduated at Yale in 1871 and was awarded his Ph.D. in 1873 for his studies in Greek and Sanskrit. Further studies of Sanskrit and comparative philology followed during a period of four years spent at Berlin and Tübingen, where he was a student under the most distinguished authorities in these subjects of the day, among them Roth and Curtius. During 1876–80 he held an appointment as lecturer on Sanskrit at Johns Hopkins University, Baltimore, and was then elected to the chair of Sanskrit in Harvard University, which he occupied for fifty-six years. During his tenure, in 1889, he travelled extensively in India with the object of securing books in his subject for the library of his University. His tour was highly successful, the accessions he acquired numbering some thousand items including both books and manuscripts. In 1890 he delivered the Percy Trumbull Lectures at Johns Hopkins, his subject being Indian poetry, and lectured at the Lowell Institute, Boston, on Indian literature and early history.

Lanman was a fellow of the American Academy of Arts and Sciences and edited the *Transactions of the American Philological Association*, of which he was secretary and in 1890 president. He also edited the publications of the American Oriental Society for some years, serving successively as its corresponding secretary, vice-president and president, holding the latter office on two occasions, in 1907 and 1919.

In addition to his editorial activities, Lanman himself published a number of works on Sanskrit, including "Hindu Drama" (1900) and "The Beginnings of Hindu Pantheism" (1890). He was also responsible, in association with the leading Orientalists of the whole world, for the Harvard Oriental series, of which forty volumes have been published, containing editions of most of the classics of the ancient East. Among the numerous honours he received in recognition of his eminence in Oriental studies, was a gold medal on the occasion of the celebration in Japan of the 2,500th anniversary of the birth of the Buddha. He was a corresponding member of the British Academy.

We regret to announce the following deaths:

Dr. C. R. M. F. Cruttwell, principal of Hertford College, Oxford, during 1930–39, on March 14, aged fifty-three.

Mr. J. P. Gilmour, editor of the *Pharmaceutical Journal* during 1916–33, on March 10, aged eighty.

Dr. E. L. Ince, lecturer in technical mathematics, University of Edinburgh, on March 16, aged forty-nine.

Prof. Mary S. Rose, professor of nutrition in Teachers College, Columbia University, on February 1, aged sixty-six.

NEW FELLOWS OF THE ROYAL SOCIETY

At the meeting of the Royal Society on March 20, the following new fellows were elected:

Prof. W. N. Benson, professor of geology, University of Otago, Dunedin, New Zealand; distinguished for his contributions to the geology, petrology and physiography of Australia and New Zealand and in particular for his studies on the ultra-basic igneous rocks.

Dr. H. J. Bhabha, Reader in theoretical physics, Indian Institute of Science, Bangalore; distinguished for his contributions to the understanding of cosmic ray phenomena, and to the fundamental theory of the elementary atomic particles.

Dr. E. C. Bullard, Smithson research fellow of the Royal Society; distinguished for his work in geophysics and for the light which his work has thrown on the structure of the Great Rift Valley and on the rock floor deep under the surface in England and the surrounding seas.

Dr. C. D. Darlington, director of the John Innes Horticultural Institution, Merton, London, S.W.19; distinguished for his researches in cytology and cytogenetics.

Mr. P. I. Dee, university lecturer in physics, Cambridge; distinguished for his experimental work in nuclear physics, in particular on atomic nuclear transformations produced artificially under bombardment by high-speed protons or deuterons.

Surgeon Rear-Admiral S. F. Dudley, C.B., O.B.E., medical director-general of the Navy (designate); medical officer in charge R.N. Hospital, Chatham; formerly director of medical studies to the Royal Navy: distinguished for his work in epidemiology and bacteriology, especially in relation to the spread of diphtheria, influenza and meningitis.

Dr. J. C. Eccles, director of the Kanematsu Memorial Institute for Pathology in Sydney, formerly Rhodes scholar (Australia) and fellow of Magdalen College, Oxford; distinguished for his physiological researches, which have dealt principally with excitation and transmission in the neuromuscular system.

Prof. H. W. Florey, professor of pathology in the University of Oxford, formerly Rhodes scholar (Australia), fellow of Gonville and Caius College, Cambridge, and professor of pathology, Sheffield; distinguished for his work in general pathology, in particular on lacteals and lymphatics and on Brunner's glands. His work on 'lysozyme' has led to its isolation in a pure form.

Mr. A. A. Griffith, research engineer, Rolls-Royce Ltd., formerly Royal Aircraft Establishment, Farnborough; distinguished for researches, ranging from pure physics to applied engineering, which have made notable contributions to the knowledge of strength of materials and to the science and development of aircraft and aero-engines.

Prof. H. W. Melville, professor of chemistry in the University of Aberdeen, formerly fellow of Trinity College, Cambridge; distinguished for his outstanding contributions in the study of gaseous reactions and of the mechanism of polymerization.

Dr. J. Needham, reader in biochemistry in the University of Cambridge, and fellow of Gonville and Caius College; distinguished for his application of biochemical methods to embryology, particularly in relation to the conditions determining embryonic and adult metabolism, and vertebrate development.

Sir David Rivett, deputy chairman and chief executive officer of the Australian Council for Scientific and Industrial Research, formerly Rhodes scholar (Australia) and professor of chemistry in the University of Melbourne. His scientific knowledge and leadership have been of great value to the Australian Commonwealth and the Empire.

Prof. Alexander Robertson, professor of organic chemistry in the University of Liverpool; distinguished for his researches on the constitution of plant products, and particularly on the important insecticide rotenone.

Prof. T. G. Room, professor of mathematics in the University of Sydney; distinguished for his work in geometry.

Mr. A. J. Rowledge, consultant engineer to Rolls-Royce, Ltd., formerly chief designer, D. Napier and Sons, Ltd.; distinguished for innovations in the design and development of internal combustion engines for motor-vehicles and aircraft.

Dr. H. Scott, assistant keeper of entomology in the British Museum (Natural History); distinguished as a field naturalist and systematist. By prolonged visits to the Seychelles, Abyssinia and South Arabia, he has greatly advanced our knowledge of the little known and fast disappearing or changing fauna of these areas.

Dr. F. E. Simon, reader in thermodynamics in the University of Oxford; distinguished for the development of new methods of liquefying helium and for his studies of phenomena at the lowest temperatures yet attained.

Dr. H. G. Thornton, head of the Bacteriology Department, Rothamsted Experimental Station; distinguished for his investigations in soil bacteriology and on the relations existing between nodule-forming bacteria and their leguminous hosts.

Mr. R. A. Watson Watt, scientific adviser on telecommunications, Ministry of Aircraft Production, formerly superintendent, Radio Department, National Physical Laboratory; distinguished for his contributions to radio engineering, particularly in relation to aerial and marine navigation.

Mr. P. Bruce White, member of the scientific staff of the National Institute for Medical Research, Hampstead; distinguished for his fundamental studies of bacterial immunology, in particular of the antigenic constituents of members of the Salmonella group.

NEWS AND VIEWS

H. E. Armstrong Lecture

ALTHOUGH H. E. Armstrong did not take an active part in the formation of the Society of Chemical Industry, he was nevertheless one of the original members, and the Society has founded a Lecture in his memory. The task of delivering the first of what will no doubt be a series of distinguished lectures, was a difficult one, and the Society could not have selected a better man than the son of 'H. E. A.' Dr. E. F. Armstrong and his father had many interests in common; they followed the same profession, they took holidays together, and, Dr. Armstrong says, he was "closest to him over nearly sixty years", being in almost daily contact with him by letter even when separated geographically. Now Dr. Armstrong has given an intimate account of his father's life and work in the form of the first Armstrong Lecture, which was delivered on February 3. The complete Lecture has been published in *Chemistry and Industry* (Feb. 8). Some of the ground covered, particularly that relating to chemical work, was dealt with by "W. P. W." in the obituary notice which appeared in NATURE of July 24, 1937. The last part of Dr. Armstrong's lecture, however, reflected more of the personal and human aspects of the 'H. E. A.' known to the present generation of men of science, and it seemed appropriate that this portion, supplementing in some ways the obituary notice, should appear in NATURE (see p. 373), where many of Armstrong's stimulating and often provocative contributions were published.

Scientific Co-operation between Great Britain and the United States

ON March 20, the president and council of the Royal Society entertained fellows of the Society and a number of friends at a buffet luncheon at Burlington House to meet Dr. J. B. Conant, the president of Harvard University. Sir Henry Dale and Dr. Conant received the guests, who numbered more than a hundred and fifty, among whom were Sir John Anderson, Lord Hankey, the High Commissioners for Australia, Canada and South Africa, and five of Dr. Conant's colleagues in his mission, namely Dr. K. T. Bainbridge, Dr. F. L. Hovde, Dr. E. J. Poitras, Dr. Warren Weaver and Dr. Carroll L. Wilson. At the conclusion of the luncheon, in the Society's meeting room, Dr. Conant gave a brief talk. He expressed his great pleasure at meeting such a representative body of British men of science, and hoped that his visit to this country would further the co-operation between scientific workers on both sides of the Atlantic, particularly in the direction of an interchange of ideas and experiences bearing on problems arising out of the War.

Emergency Scientific Research Bureau in Eire

THE Government of Eire has set up a small advisory body, to be known as the Emergency Scientific Research Bureau, to deal primarily with the technical problems involved in the provision of substitute processes and materials during the period of the emergency. This body, which will be attached to the Department of the Taoiseach, has the following terms of reference: (1) To give technical advice to the Government on such special problems relating to industrial processes and the use of substitute materials as may be referred to them. (2) To advise the Government generally on the use of native or other materials to meet deficiencies caused by the restriction of imported raw materials and commodities. (3) To direct or conduct special researches and inquiries connected with the above.

The following have been appointed to be members of the Bureau: Prof. J. J. Dowling (chairman), professor of technical physics, University College, Dublin; Dr. J. J. Drumm; Prof. M. A. Hogan, professor of mechanical engineering, University College, Dublin; Prof. J. H. J. Poole, professor of geophysics and experimental physics, Trinity College, Dublin; Dr. T. S. Wheeler, State chemist. The secretary to the Industrial Research Council, Dr. J. J. Lennon, will act as secretary to the Bureau. The Bureau will utilize the premises of the Industrial Research Council, 45 St. Stephen's Green, Dublin.

University College, Cardiff: Air Raid Damage

UNIVERSITY College, Cardiff, has suffered to some extent in recent air raids, the most extensive damage being at the Students' Union building. The refectory of the Union, which was erected with money collected by students as a memorial to those students who lost their lives in the War of 1914–18, has been wrecked, and will probably have to be rebuilt, while the rest of the Union premises have also been badly shaken. Fortunately the new gymnasium, recently completed at a cost of £17,000, escaped almost untouched. The Cathays Park buildings of the College suffered from blast, many windows and almost all the roof lights being destroyed. The Tatem Laboratories were the most affected, and blast caused a considerable amount of damage internally to fittings and apparatus in both the Physics and the Chemistry Departments, though not enough to put these Departments out of commission for more than a few days. A fire was started in the Drapers' Library but was quickly extinguished by the fire watchers. Fire watchers at the Union luckily escaped serious injury, but one of the watchers in the College buildings has unhappily died of injuries received in the course of his duties. A young assistant on the staff of one of the visiting institutions which are at present working in University College, Cardiff, was also killed at his lodgings in the town. These casualties have caused deep regret.

Cost of Living for Working-Class Families

A FURTHER publication in the New Merseyside Series issued by the Statistics Division of the Social Science Department, University of Liverpool, deals with the cost of living of representative working-class families (Liverpool: University Press. London: Hodder and Stoughton, Ltd. 1*s*.). A household consisting of father, mother and young children has been selected as representative, as well as a widow supporting two children of school age, and a husband and wife, both old-age pensioners. Essential needs are sub-divided under the usual five heads: food, clothing, rent and rates, fuel and light, sundries. In regard to food, the findings of the report of the British Medical Association Committee on Nutrition have been taken as one basis, but the specimen diets were modified to satisfy rationing regulations and to permit greater variety in diet and elasticity in cooking. The poverty standard selected is that adopted for the Merseyside Survey. The report indicates that between June 1933 and October 1940, expenditures showed increases of 57·5 per cent, 64 per cent and 76 per cent respectively for the family, widow with children, and old-age pensioners.

Comparing the estimated basic needs of these representative families, poverty standards, actual expenditure, and income from the social services, the inquiry indicates that the services concerned succeed in finding a close approximation to the cost of bare subsistence, though this is appreciably below the human needs standard. The blot on the social services is the absence of adequate provision of assistance for sick persons and their families, and the reduction in benefit when work is lost on account of illness. The report includes an analysis of actual expenditure of three typical non-earning families as well as of the average expenditure of 8,905 families, and a comparison with human needs, which suggests that the British Medical Association diets are what they were intended to be, estimates of the *minimum* expenditure on food necessary for health and working capacity. The sums spent on rent, fuel and light in the average budget are also rather higher than those allotted on the human needs standard, but the difference between the two results under the head of clothing is insignificant. The total average household expenditure revealed in the budgets collected by the Ministry of Labour is 50 per cent higher than the estimated cost of living at the human needs level.

Hindu Iconography

A VALUABLE collection of paintings and bronzes of international repute illustrating Indian art and religion has recently been added to the national collections by donation to the Department of Oriental Antiquities of the British Museum (Bloomsbury). It has been given by Mrs. E. C. Moor and was formed by her husband's grandfather, Major Edward Moor, F.R.S. (1771–1848), while gathering material for his pioneer work "The Hindu Pantheon" (1810). The collection consists of 609 objects, of which 360 are bronzes and 249 are paintings and drawings. The paintings, which with the bronzes were for the most part acquired through a pandit of Poona, to whom Moor refers and who identified the subjects, are Decani in style. Some belong to an eighteenth century Rajput school, while the most important illustrate verses by the poet Keśava Das of Bundelkund (1555–1617) and were probably executed at Jaipur in the early eighteenth century. The majority of the bronzes are of seventeenth century or eighteenth century date. The value of the collection lies in its original purpose as illustrating Hindu iconography; and as is pointed out in an account of the collection (*Brit. Mus. Quarterly*, 14, 4; 1940), since not all of them were used in "The Hindu Pantheon" and those that were engraved for publication were "made more handsome", there is room for much fresh work on the collection. It is hoped that it will provide the nucleus of a study collection for students of Indian art and religion.

Birds of North-West England

A LIST of 270 species and five subspecies together with much original information on bird habits and movements resulting from some twenty years field-study of bird life in the area between the Ribble and the Dee and inland to Warrington were given on February 13 in a paper to the Liverpool University Biological Society by Mr. Eric Hardy, an honorary member, who reviewed the results as they had been drawn up for the Merseyside Naturalists' Association's proposed handbook on the birds of the area. Much of this work might seem idle in war-time, but the bird census and survey have disclosed items of economic importance such as the distribution and habits of useful and harmful birds on the land, which are being sent to the Royal Lancashire Agricultural Society. The increase in the distribution of wild duck, waders, gulls, crows, owls, etc., and the decrease of other birds is of more than natural history interest.

The bird census showed an average density of 6·7 birds to the acre; the house-sparrow, which forms 38 per cent of the bird population of a Liverpool suburban park, forms only 2 per cent of the population of rural Knowsley Park. Mr. Hardy pointed out that a knowledge of the economic position of bird life in an area is essential to war-time agricultural efforts in order to know what to protect and what to repress—an undertaking too often treated from a national rather than a local attitude. It has often been stated that we could not live more than nine years without birds owing to the ravages of insect pests they control; but modern field work has shown that a greater toll of insect pests like caterpillars is taken by predatory insects.

Spike Disease of Sandal

THE spike disease of sandal was first noticed forty years ago and since then numerous investigators have studied the problem. For the most recent account of the disease the reader is referred to an article by Rao Sahib S. R. Iyengar and A. L. Griffith (*Indian Forest Records*, 6, No. 4). Work so far carried out has led to the conclusion that it is an insect-borne disease. The vector is of such a size that it can pass through a mesh of $\frac{1}{4}$ in. but is excluded by one of $\frac{1}{20}$ in. The average period from infection to manifestation of the disease is approximately 7 months in the case of natural infection and $4\frac{1}{2}$ months with artificial infection. From manifestation of the disease until death of the tree, the average period is about 15 months but varies with the girth of the tree. The transmission of the disease to healthy trees by grafting can be carried out most easily by a semi-trained staff, by leaf-grafting. Successful transmission by means of any particular insect has not so far been carried out, but suspicious spike-like symptoms have appeared in seven cases. Grafting, however, failed to transmit these same symptoms to healthy plants. While the vector is as yet unknown, the available evidence points to its being an uncommon species of insect of the order Hemiptera.

Science Masters' Association

It is satisfactory to learn from the report of the Science Masters' Association for 1940 that the membership remains almost stationary and that the schools represented, now more than 950, show a slight increase. It is suggested that meetings of the eight branches of the Association, which were discontinued last year, should be started again in spite of difficulties, and that the Examinations' Sub-Committee might receive more criticisms from members. This work is most useful, and every effort should be made to keep it up.

Motor-Vehicle Industry in Great Britain

According to an article in *Engineering* of January 31, new registrations of private cars in Great Britain in the first seven months of 1940 totalled only 30,200, compared with 194,500 in 1939. Since July 1940, new registrations have been taken out at the rate of only 200–300 a month. New registrations of commercial vehicles up to July were about one quarter of the corresponding figures for 1939; after July, however, there was a fall from an average of about 1,400 a month to about 300 a month as the result of the ban on sales except by special permit. Exports of private cars from the United Kingdom in 1931 numbered 17,104; in 1937 the figure was 53,655; and in 1939 it was 35,190 during January–August and only 8,040 during September–December. These figures show that the rate of export of complete cars and chassis was approximately halved as the result of the outbreak of war. A comparison of British exports and new registrations during the early months of 1940 suggests that the production of private cars was probably at the rate of 6,000 a month. This compares with about 30,000 a month during the early months of 1939 and a peak production of more than 32,000 a month in 1937. The production of private cars for the home market had thus become only a subsidiary function of the industry, the main functions of which were the provision of trucks and lorries for the Army and assistance to the aircraft industry.

On the retail side, the reduction in the sales of new vehicles has resulted in an appreciable fall in turnover of most of the firms in the industry, though this fall has probably been very much less than was anticipated at first. During the winter of 1939–40, about half a million motor-cars were laid up—approximately a quarter of the total number in use. Many of these were put back on the road in the spring. For the quarter ended June 30, 1940, receipts from motor-vehicle taxes were £850,000 higher than for the corresponding quarter of 1939. This must be considered very satisfactory, especially in view of the increased rate of tax. Motor-cycles were excluded from the ban on sales of motor-vehicles imposed in July. Up to August 1940, home sales were at the rate of about 3,000 a month, compared with rather more than 5,000 in the preceding year. A significant feature of the sales during 1940 was the high proportion of the total accounted for by motor-cycles of less than 150 c.c. capacity. These have consistently accounted for between 70 and 80 per cent of the total sales, whereas for 1939, the corresponding proportion was only about 25 per cent. It is to be hoped that the impetus given by petrol rationing to the development of the small machine in Great Britain will encourage British exporters to meet foreign competition at the end of the War.

Diesel-Engine Driven Generating Station

A new electric-generating station has been installed at Port Macquarie, which is a seaside town at the mouth of the Hastings River, New South Wales. The power is supplied by three Diesel engines furnished by Messrs. Blackstone and Co., Ltd., Stamford, Lincs, directly coupled to alternators having a combined output of 500 kilowatts. Two of the engines are 240 b.h.p., six-cylinder units, and the third is a 120 b.h.p. three-cylinder engine. The engines are of the latest totally enclosed design, and as the plant has to run unattended for part of the day, an alarm signal has been installed, which is claimed to give complete protection against accidents, such as an excessive rise in the lubricating oil temperature, failure of the cooling-water flow, overspeed or overloading, failure of the oil pressure or excessive temperature of the cooling water. If the alarm is not attended to within five minutes, the engine automatically stops and no damage is done. The engine room measures 70 ft. by 31 ft., and a special fuel room is provided, the fuel entering the engine room through a trench, which also accommodates the air, lubricating oil, and cooling-water pipes.

Comets

Comet Friend-Reese. Harvard Card 560 announces that Mr. Clarence L. Friend, Escondido, California, discovered a comet on January 17. It was discovered independently by Mr. E. J. Reese, Uniontown, Pennsylvania, and was described as diffuse with a nucleus, tail less than 1° in length, magnitude 10. Messrs. K. Guthe and R. M. Thomas of the Harvard Observatory have determined a position of the comet from a pre-discovery image on a Harvard plate taken with the *FA* camera (Cambridge, 1·5 in. aperture), and from a plate taken with the *I* camera (Cambridge, 8-in. aperture). The first was on Jan. 0·9908 and the other on Jan. 29·00698, and from these and an observation on January 19 they have computed the following orbit :

T	1941 Jan. 20·633 U.T.	
ω	132° 35·9′	1941·0
Ω	329 2·9	
i	26 36·5	
q	0·94285	

Comet Encke. Harvard Card 561 announces that Van Biesbroeck, Yerkes Observatory, reports the discovery of this comet on Jan. 19·033. It is described as diffuse with a nucleus, the magnitude being 17. In the "Handbook of the British Astronomical Association, 1941", the late Dr. A. C. D. Crommelin gave the elements and an ephemeris, and the comet is very close to the predicted position.

Comet Paraskevopoulos (1941 *c*). This comet was discovered by Dr. John S. Paraskevopoulos, of the Boyden Station, Bloemfontein, on January 23, and also by Dr. R. Grandon and others. Its magnitude was stated to be 3·5 and its tail was 5° in length. An orbit computed by Wood and Jackson, and cabled by Dr. John Jackson, Cape of Good Hope, is given below, and also an ephemeris :

T	1941 Jan. 27·779 U.T.	
ω	268° 26′	1941·0
Ω	41 50	
i	168 08	
q	0·7894	

1941	R.A.	Dec.	ϱ	r
March 27	2h 08m	+11·3°	2·124	1·327
31	2 10	11·8		
April 4	2 11	12·3	2·323	1·435
8	2 13	12·7		
12	2 14	13·1	2·497	1·544

Comet Okabayasi – Honda (1940 *e*). This comet was discovered at Tokyo on October 4 and was described as being of magnitude 11 and possessing a nucleus. The elements of an orbit and also an ephemeris, computed by Miss E. L. Scott and Mr. H. A. Panofsky, of the University of California, are given below :

T	1940 Aug. 15·8440 U.T.	
ω	329° 50′ 16″	1940·0
Ω	127 15 15	
i	133 07 30

The Night Sky in April

THE moon is full on April 11 at 21h. and new on April 26 at 13h. U.T. A naked-eye star, ο Leonis (mag. 3·8) is occulted on April 7, the disappearance, as seen from Greenwich, taking place at 21h. 43·5m. at position angle 58° from the north point of the moon's image. Jupiter and its companion, Saturn, are planets of the evening sky. Both will soon be too close to the sun for observation, but they will re-emerge as morning stars towards the end of June. Mars continues as a morning star, and is 5° above the eastern horizon about 3h. 30m. U.T. in mid-April. The distant planet, Neptune, is not far from β Virginis and comes to the southern meridian shortly after 22h. U.T. in mid-April (add 1 h. to convert to Summer Time). This planet, seen as a star of magnitude 8, requires for its detection some telescopic aid and a section of a star map for guidance such as is given in the "Handbook of the British Astronomical Association, 1941", p. 9. In the same constellation is one of the best-known binary stars, γ Virginis. The components are of nearly equal magnitude (3·6 and 3·7 respectively) and their present separation is 5¾″; the period is about 180 years. The Lyrid meteors are most frequent about April 20, their radiant point being near 104 Herculis, that is, south-preceding the bright star, Vega.

Announcements

DR. F. C. HAPPOLD, lecturer in biochemistry in the University of Leeds, has been elected to the recently instituted readership in biochemistry.

THE Herbert Jackson Prize of the London, Midland and Scottish Railway for 1940 has been awarded to Mr. S. C. Britton, of the Metallurgical Department (Engineering Section), Derby, for his paper entitled "The Corrosion of Copper and some Copper Alloys in Atmospheres highly polluted with Coal Smoke".

THE Chemical Society will attain its centenary on March 30, and will hold the hundredth annual general meeting at Burlington House on Thursday, April 3. The business portion of the meeting will be at 12 noon when the election of Prof. J. C. Philip as president, and of those fellows nominated to fill vacancies among elected ordinary members of Council will be announced. At 2.45 Sir Robert Robinson, the retiring president, will deliver his presidential address entitled "The Mechanism of the Benzidine Rearrangement and some Related Topics". Arrangements for the celebration of the centenary of the Society have been postponed until after the War.

AT the annual general meeting of the Royal Astronomical Society held on March 14, the following officers were elected for the ensuing year : *President*, Prof. S. Chapman ; *Vice-Presidents*, Prof. David Brunt, Sir James Jeans, the Rev. T. E. R. Phillips, Prof. H. C. Plummer ; *Treasurer*, Mr. J. H. Reynolds ; *Secretaries*, Mr. D. H. Sadler, Dr. A. D. Thackeray ; *Foreign Secretary*, Sir Arthur Eddington.

THE publication "Rubber and its many Uses", by H. McKay, in "The Empire at Work" series (Oxford University Press, 1940) deals, in 76 pages, and in very simple language with the production of rubber in the plantation and the way in which it is manufactured into various articles such as sponges, tubes, tyres, tennis and golf balls, and hard rubber. The whole is well illustrated. The price is 10*d*.

LETTERS TO THE EDITORS

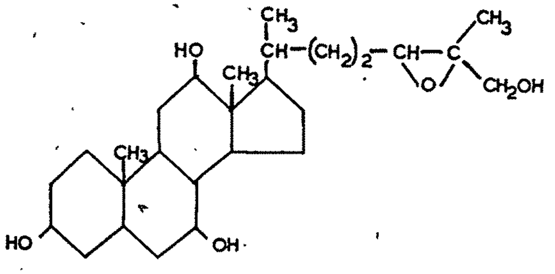
The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

Bile Acids of Elasmobranch Fish

THE bile of bony fishes, like that of birds and mammals, contains acids in which glycine or taurine is conjugated with mono-, di-, and tri-hydroxy derivatives of cholanic acid. On the other hand, Hammarsten[1] isolated from the bile of the shark, *Scymnus borealis*, acids which he showed to be sulphuric esters of neutral compounds, chiefly α-scymnol. The constitution of scymnol has been largely elucidated by the investigations of Windaus, Bergmann and König[2], and of Tschesche[3], who have shown that the compound is related to the commoner bile acids, but contains eight carbon atoms in the side chain like cholesterol, whereas the usual bile acids contain only five. This has considerable bearing on the view that the bile acids arise from the degradation of cholesterol, and it has been suggested[2] that the shark, which belongs to a primitive order of fish, lacks the ability to effect more extensive oxidation of cholesterol to the bile acids. This is evidently not entirely true, for Ota[4] has recently isolated cholic acid as well as scymnol from the bile of a species of shark found in Japanese waters.

The correspondence in positions and configurations of the nuclear hydroxyl groups of scymnol and cholic acid has been established by Ashikari[5] who degraded scymnol to cholic acid. The following is accordingly the structure of scymnol, the evidence for the ethylene oxide ring being somewhat inconclusive.



The scymnol used by Ashikari was isolated from the bile of *Dasyatis akajei*, a species of sting ray found in Japanese waters. An examination has now been made of the bile of the blue skate, *Raia batis*, and the grey dogfish, *Squalus acanthias*, caught off the Faroes during the summer and autumn. Immediately after the fish were killed the gall bladders were squeezed into a large excess of absolute alcohol, and the alcoholic bile was afterwards worked up as described by Windaus *et al.*[2] Pure scymnol, m.p. 192–193° (corr.) was readily isolated in considerable quantity, from the bile of both of these cartilaginous fish. It had $[\alpha]_D^{18°} = + 39{\cdot}4°$ ($c = 2{\cdot}614$ in alcohol, (found: C, 72·1; H, 10·1. calc. for $C_{27}H_{46}O_5$, C, 71·9; H, 10·3 per cent). There were minor amounts of resinous bile acids from which a pure component has not yet been isolated. Alkaline hydrolysis of the bile from the teleostean angler fish (*Lophius piscatorius*) gave no water-insoluble product so that scymnol-sulphuric acid was not present. Scymnol, esterified with sulphuric acid, thus appears to be a characteristic major component of the bile of elasmobranch fish.

The scymnol obtained from the skate bile was further characterized by conversion into the dihydrate[6], the hydrochloride[2], and the tetra-acetyl derivative[3] (this was prepared by Dr. J. D. Loudon). In preliminary experiments on the isolation from both skate bile and dogfish bile complications arose from the fact that purification of the crude dihydrate by crystallization from ethyl acetate gave a product which formed colourless slender needles, m.p. 138–140°. This evidently still contained water of crystallization. (Found: C, 70·7; H, 10·4. $C_{27}H_{46}O_5,\frac{1}{2}H_2O$ requires C, 70·5; 10·3 per cent.) Its formation was apparently associated with the quality of the ethyl acetate, for it was rapidly and completely transformed into anhydrous scymnol when warmed with pure ethyl acetate obtained from another source.

This investigation, which is being continued, was made possible by the co-operation of Dr. J. A. Lovern, of the Torry Research Station, Aberdeen (Department of Scientific and Industrial Research) who kindly arranged for the collection of the bile.

Insect Cuticle as an Asymmetrical Membrane

IN a recent communication[1], I provided evidence to show that the permeability of the outer 'lipoid layer' of insect cuticle to feebly dissociating substances of high dielectric constant may be greatly increased by relatively apolar substances of low dielectric constant. Since then I have obtained similar results for the outer cutinized layers of a number of plant epidermal membranes. The physical and chemical properties of plant 'cutin' are said to resemble those of the insect 'epicuticle' or 'lipoid layer'[2], and this suggested that induced penetration of polar substances was not a fundamental characteristic of insect cuticle, but might take place with relatively simpler artificial membranes.

The permeability of thin rubber membranes was found to be similar to that of insect 'epicuticle' or plant 'cutin'. Rubber swells readily in oils of low dielectric constant such as kerosene, but imbibes relatively small proportions of oils of higher dielectric constant such as oleic acid or castor oil. Rubber membranes are only slightly permeable to ethyl alcohol, but the presence of kerosene in the disperse phase of the membrane framework increases the permeability of the membrane to ethyl alcohol, which is miscible with kerosene. This effect is negligible with oleic acid or castor oil.

Similar considerations apply to other membrane systems. Collodion imbibes 'gelifying liquids' such as ethyl or propyl alcohols, whereas kerosene is less readily imbibed and will precipitate collodion from solution in a mixture of ethyl alcohol and ether. 'Cellophane' and parchment membranes imbibe water more readily than ethyl alcohol or kerosene. As with collodion, the permeability of such membranes to ethyl alcohol is not increased by oils of the kerosene type. These observations stress the importance of the physico-chemical relation between a membrane and permeating substance in determining whether the permeability of the membrane to this particular substance might be modified by the introduction of other components into the system. Generally, it would appear that the permeability of apolar hydrofuge membranes to relatively polar substances is increased by substances of intermediate polarity which are more readily imbibed by the membranes. The degrees of induced penetration will depend partly on the mutual solubilities of the mixture of permeating substances, and partly on the rates at which the polar substances diffuse from the membranes. This generalization also applies to the induced penetration of apolar substances through relatively polar hydrophil membrane systems. The application of some of these results to insecticidal work may be shown by the fact that a mixture of ethyl alcohol and kerosene is very toxic to larvæ of the blowfly Calliphora (*vide* Hurst[1]), but mixtures of ethyl alcohol with oleic acid or castor oil are only slightly toxic.

Insect cuticle possesses a high degree of asymmetry depending on the association between the external hydrofuge 'lipoid layer' and the internal hydrophil protein-chitin complex. This asymmetry has an important effect on the permeability of the whole cuticle, and is modified in different insects by the relative distribution and physical properties of the soluble and insoluble components of the cuticle framework. The effects of such asymmetry on permeability may be demonstrated with artificial membranes prepared by impregnating one surface of parchment with collodion or rubber. The simplest approach is to consider the behaviour of the permeating substance within the membrane framework. Each substance diffuses most readily towards that region of the membrane which offers least resistance to its penetration, so that under standard conditions the whole membrane is more permeable in this direction. Experiments have shown that the rate of evaporation of solvents through asymmetrical membranes is greater in the direction of more rapid diffusion.

The differences in permeability in opposite directions through a membrane have long been known to workers with animal membranes[3]. Similar results have been obtained for artificial membranes[4] and plant membranes[5], and it was supposed that this behaviour was due to the 'double' nature of the membranes. The present results throw some light on the underlying mechanism of this behaviour. The importance of asymmetry in membrane permeability is shown by the fact that combinations of asymmetrical membranes may be more permeable to a particular substance than the *single* components of the membrane systems. Water evaporates through the cuticle of Calliphora larvæ more than one hundred times as rapidly in the direction lipoid layer → chitin layer than in the opposite direction, while there is an intermediate rate of evaporation through two such cuticles in which the lipoid layers are in contact. Using various solvents, similar results have been obtained with a number of insect cuticles, plant membranes and artificial asymmetrical systems.

Membrane system		Permeating solvent	Direction of more rapid diffusion	Direction of max. rate of evaporation
A	*B*			
Rubber	Parchment	Water	$A \rightarrow B$	$A \rightarrow B$
,,	,,	Ethyl alcohol	$B \rightarrow A$	$B \rightarrow A$
,,	,,	Kerosene	$B \rightarrow A$	$B \rightarrow A$
Collodion	Parchment	Water	$A \rightarrow B$	$A \rightarrow B$
,,	,,	Ethyl alcohol	$B \rightarrow A$	$B \rightarrow A$
,,	,,	Kerosene	$A \rightarrow B$	$A \rightarrow B$

In the living insect, the cuticle asymmetry is partly regulated by the free lipoid in the outer 'lipoid layer', which is specially adapted to maintain a physiological balance in each particular cuticle. This balance may be upset when the free lipoid from one insect cuticle comes in contact with the cuticle of another. When Calliphora larvæ are allowed to remain in contact with the relatively hard-bodied Tenebrio larvæ, the latter gradually lose water by excessive evaporation and die from desiccation, while there is no increase in the rate of water loss from the soft-bodied insects. This has been correlated with the fact that the free lipoid in the cuticle of Calliphora is distinctly more hydrophilic than that in the cuticle of Tenebrio; a similar desiccation takes place when hard-bodied insects are smeared with lecithin. This does not occur, however, with hard chitinous structures, such as blowfly puparia, where the high degree of impermeability is largely dependent on the insolubility and rigidity of the condensed chitin-protein complex.[6]

In biological systems, asymmetrical colloidal associations occur at various protoplasmic interfaces. The present work indicates that the permeability of such complex associations is not necessarily deducible from summation of the permeabilities of the component phases and suggests a need for reconsideration of certain fundamental assumptions concerning the permeability of membranes.

This work was made possible by means of a grant made to the Imperial College by the Department of Scientific and Industrial Research, and a full account will be given elsewhere.

Isolation of Rhamnose Derivatives from *Ulva lactuca*

Working on algæ other than the Chlorophyceæ, various investigators have established the existence of algal polysaccharides containing mannuronic, galactose or fucose residues, the two latter being in the form of sulphuric acid esters. An investigation of *Ulva lactuca*, a member of the Chlorophyceæ, undertaken with the hope of ultimate correlation with pigmentation, has unexpectedly revealed the presence of a rhamnose polysaccharide, hitherto unknown among algal products.

Without a complete purification of the weakly acidic, non-reducing Ulva carbohydrate, evidence was obtained for an acid sulphuric ester structure and the absence of uronic acid residues. By furfural estimation a methyl pentose content of approximately 25 per cent was established, and on hydrolysis by dilute acids, preferential fissure of the methyl pentose residues occurred to some extent.

Rhamnose was identified as a constituent of the hydrolysate, by a fractional distillation after methylation of the syrupy sugar mixture, and the subsequent isolation of crystalline 2 : 3 : 4-tri-methyl rhamnose anilide and 2 : 3 : 4-tri-methyl rhamnose phenyl hydrazone.

Interruption of this work has prevented the complete identification of a very labile constituent of the hydrolysate. Investigation of the other hydrolysis products, together with an investigation of the methylated polysaccharide, will be undertaken as soon as the work can be resumed.

Tadpoles out of Season

By pituitary treatment of an appropriate species of Rana at the appropriate time of year it has been shown by Rugh[1] in the United States that fertilized eggs and developing tadpoles can be obtained the whole year round. I have found that during the winter months (November–February) fertilized eggs and tadpoles of *Rana temporaria* can be readily obtained by the same methods, although the reaction of this species to pituitary treatment is somewhat different.

Briefly, Rugh's techniqueis to inject in saline the whole *partes anteriores* of pituitaries freshly excised from frogs of the same species, into the cœlomic cavity of the adult frog by means of a large hypodermic needle. By controlling the dose and time of injection, amplexus in the male can be made to synchronize with ovulation in the female. In the frogs used by Rugh (*Rana pipiens*, *R. clamitans*, *R. catesbeiana*, *R. sphenocephala*, *Acris gryllus*) egg-laying follows treatment within twenty-four hours at room temperature, although it may be delayed up to five days by smaller doses. In *R. temporaria*, however, a period of about twenty-one days elapses between injection and egg-laying in the female and about eighteen days between injection and amplexus in the male, so that fertilized eggs may be expected about the twenty-first day. Moreover, these times appear to be little affected by variations in dosage, so that control is simple. A single peritoneal injection of 0·25 c.c. of saline containing anything from three to six glands excised from adult females will produce ovulation or amplexus. Six glands excised from adult males will suffice instead. When the frogs begin to copulate each pair should be placed in a separate vessel containing fresh pond water. After the spawn is shed and fertilized some three days later, the frogs should be removed. The tadpoles produced in this way appear to be in every respect normal.

Soil Protozoa in some Chinese Soils

Forty soil samples collected around Kiating and its vicinity, Szechuen, have been studied. Fifty-seven species of Protozoa were recorded: 24 species flagellates, 10 species Sarcodina and 23 species ciliates. Among them, several species were found for the first time in soil. They are, among the flagellates, *Cryptochrysis commutata*, *Peridinium* sp.; among the Sarcodina, *Amœba guttula*, *Amœba striata*; and among the ciliates, *Frontonia* sp., *Chilodon capucinus*, *Chilodon fluviatilis*, *Vorticella chlorostigma*, *Vorticella nutans*. The most common species found are *Oikomonas termo*, *Monas vulgaris*, *Amœba limax*, *Hartmanella hyalina*, *Cercomonas longicauda*, *Nægleria gruberi* and *Colpoda cucullus*. They are present in 70–100 per cent of the samples examined. Casual observations indicate that the greatest number of species found in one single sample is around seventeen, and the least one or two.

The numbers of Protozoa per gram of soil were determined by the dilution method for twenty soil samples. The highest number found was 112,500 (rice field, clay) and the smallest number 65 (barren sand, loamy sand). Flagellates are present in far greater numbers than the Sarcodina and ciliates.

Discreteness of Sensations

In 1938 I observed the fluctuation of the threshold of hearing[1]. As proved by recent experiments, this phenomenon is also applicable in the field of vision and touch, and is characterized by the discreteness of sensations.

The phenomenon has been investigated in the following way. The observer receives auditory, visual or tactual impulses of equal duration (0·3 sec.) at equal intervals (0·45 sec.). As the force of the impulse decreases, the impulses become less clear or loud, and they seem to be of lesser duration, according to the integral law of apparent duration[2], but all remain exactly alike as compared with one another. With a further decrease in the force of the impulse, there comes a moment when one or another impulse ceases to resemble the others and appears shorter. This moment is defined as the 'beginning of fluctuation'. When the force of the stimulus is still further decreased, there is a new moment when one or the other impulses vanishes completely—'middle of fluctuation'. The next moment, when all of the impulses vanish, is considered the individual threshold of sensitivity of the given observer, *i*.

Numerous measurements have shown that the beginning of fluctuation comes when the intensity of the stimulus is four times the individual threshold (6 db.), and the middle of fluctuation comes when the intensity is 1·6 times the threshold (2 db.). The intensity of 0·6 of the threshold (0·6 *i*) represents the amplitude of fluctuation, and one and the same values were obtained for hearing, vision and touch. The same value of 0·6 of the threshold was obtained for hearing within the limits of 200–3,000 Herz, although the sensitivity of the ear changes 1,000 times within this range.

The phenomenon of fluctuation of the threshold of sensitivity can be explained if we realize that our sensations increase in jumps, or steps, and, furthermore, that the size of each such step is equivalent to the amplitude of fluctuation, that is, to 0·6 *i* (where *i* is the threshold of sensitivity). I find five such steps, after which they become unobservable as compared to the increased loudness. (Fig. 1).

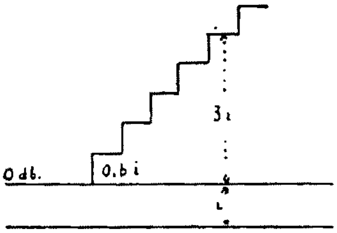

Fig. 1.

Another series of experiments which confirms these results consisted of the following:

A number of impulses having a duration of 0·75 sec. were given, one after the other, at intervals of 0·75 sec. Further, two impulses were given simultaneously, one for vision (a neon lamp connected to a case having an opening of 0·5 cm.), and the other for hearing (a telephone). Thus both impulses are received at the same time. The visual impulse serves as an indicator and its brightness remains constant throughout the duration of the experiments; the loudness of the sound impulse changes. At the beginning, both impulses are of the same duration—both begin and end simultaneously (Fig. 2*a*). As the loudness is decreased, the sound impulse begins to lag, at first scarcely noticeably (Fig. 2*b*); later it lags by half the visual impulse (Fig. 2*c*), and at the end there remains but one element of sensation, one sound dot at the end of the visual impulse (Fig. 2*d*). This takes place when the intensity of sound is equal to 1·6 *i* (when the loudness is 2 db.), that is, exactly at an intensity which corresponds to the middle of fluctuation.

The time by which the sound impulse lags corresponds exactly to the time necessary for the accumulation of the elementary work of sound (1·6 *it*), which is necessary for one element of sensation.

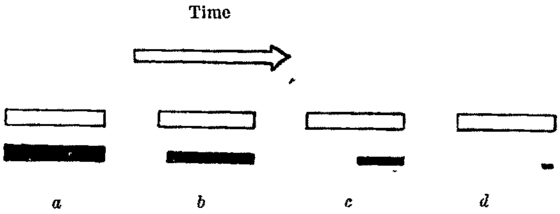

Fig. 2.

The experiments confirmed very well the equation connecting the intensity of sound, *I*, the individual threshold of the observer, *i*, the duration of the impulse, *t*, and the extent of the lag Δt:

$$10 \lg \frac{I}{i} = 2 + 10 \lg \frac{t}{\Delta t} \qquad (1)$$

The visual and sound impulses can be interchanged: the sound will then serve as an indicator and the visual impulse will vary in brightness. The visual impulse will then lag and will be shortened, as shown in Fig. 2. The element of visual sensation will be obtained when the intensity of light is equal to 1·6 *i*, and the time of the lag can be determined from equation (1). Experiment has shown that the same thing occurs with the tactual impulse. In this case, the indicator may be either the visual or the sound impulse.

Other experiments with impulses of greater duration have shown that the time for the accumulation of the elementary work of the impulse may reach many seconds.

Catalysis by Activated Copper Sulphide

60 gm. carefully purified acetaldehyde and 30 gm. copper sulphide, activated by oxidizing a part of its surface into cupric sulphate, were sealed in a tube of Pyrex glass and kept at 15–20° for 24 days. At the end of this time, 60 per cent of the reactant was converted into paraldehyde, which was identified by determining the boiling point, the melting point and the mixed melting point with an authentic sample. In a control experiment without catalyst, 98 per cent of the acetaldehyde could be recovered.

It follows that the activated copper sulphide is a catalyst not only for the conversion of certain petroleum hydrocarbons[1] but also for a low molecular polymerization involving the opening of a carbonyl bond.

STONE AGE MAN IN CEYLON

P. E. P. DERANIYAGALA has written an important paper entitled "The Stone Age and Cave Men of Ceylon (*J. Roy. Asiatic Soc.*, Ceylon Branch, **34**, 92; September 1940). Before 1936, the conclusions at which specialists had arrived relating to the prehistoric stone artefacts of Ceylon were extremely divergent owing to the absence of glacial deposits and of vertebrate fossils upon which these conclusions might be based. The second impediment no longer exists. Recent discoveries of an extinct hippopotamus, rhinoceros and race of elephant associated with stone artefacts may, it is argued, be assigned to the Upper Pleistocene, being younger than the Narbudda deposits of the Middle Pleistocene in which the hippopotamus occurs with three extinct proboscidian genera. The presence of the lion fossil and the absence of tiger and king cobra in Ceylon suggest that the island's extinct fauna entered before the last two descended far into peninsular India, while the absence of the horse indicates that the large extinct mammals entered Ceylon after the extinction, temporary or final, of this ungulate in India. If this be correct, these fossils of Ceylon must be regarded as comparatively recent; nor can the primitive stone artefacts be held to be the earliest handiwork of man, while the hitherto unexplored river terraces may reveal an earlier phase when stone cultures began in the island.

Man possibly entered Ceylon before developing the technique of making implements of stone, and acquired this art independently after the isolation of the island. Lacking the incentive of northern invasian which affected his continental relatives, he failed to advance beyond a phase akin to the Abbevellian, in which indeed he remained almost to the end of the early stone age culture of Ceylon in Pleistocene times or later. The poorly developed second phase of early stone age culture was replaced by the neolithic by a transition sufficiently abrupt to suggest that Ceylon's palæolithic man accompanied the hippopotamus and other large mammals into extinction, possibly as a result of an arid spell. The further possibility exists that when India and Ceylon were reconnected, the stone age races of India overran the island, and palæolithic man, if not already extinct, was unable to withstand their superior numbers and more efficient weapons.

The tendency of the Veddas to throw back to two physical types differing from other races in Ceylon, suggests that more than one neolithic race entered the island, a view supported by the occurrence in India of certain ancient pre-Dravidian races—Irula, Panyan, Kurumba, etc.

During Pleistocene times and later, Ceylon seems to have been united with India during both warm and cold spells. The final separation was still incomplete even so late as early historic times, as appears in the Ramayana. In addition, the topography of Ceylon fluctuated considerably, earth movements apparently bringing about a swift river phase, which was replaced by a phase of slow rivers and lakes, followed by further movement in which the lakes and many rivers disappeared, leaving only small streams or a series of swamps. The broad valley between the central mountain mass of Sri Padhé, or Adam's Peak, and the outlying range to its south-west is a source of fossils and artefacts, which also occur in the adjoining strike valleys. These comprise the Ratnapura series, which display much superficial laterization, possibly as a result of the south-west monsoon.

As the best evidence, both palæontological and archæological, is derived from the deposits of the strike valleys of this area, it is proposed to give to this stone age culture the name *Ratnapura*. It comprises two phases, of which the lower and earlier is extremely crude without any well-defined general shapes, has a crude flaking technique with scarcely any retouching, and contains a considerable proportion of pebble artefacts. The implements are about half the size of the quartzite palæoliths of Madras and show more affinity to the early Soan of Northern India. The materials employed are chert, quartz, corundum and jasper. The upper Ratnapura implements are smaller than those of the lower culture, and show some attempt at retouching, scraper-like forms and the commencement of a crude hand-axe; and also entire crystals of quartz or corundum, sometimes flaked to a sharp edge at the apex and roughly chipped, were employed. The upper phase did not develop far before it became extinct.

The relative scarcity or absence of palæoliths from the highest of the peneplanes of Ceylon suggests that during palæolithic times this region was too cold for autochthonous tropical races, as it is partially to-day. Since neolithic implements abound here, it is possible that either one neolithic race was driven into the cold area by another, or that all the neolithic races were forced into it by the advent of metal-using man. Being thus thrown together, they interbred and degenerated into the so-called Veddas, who never manufactured metal implements and use shells for this purpose down to the present day. Neolithic man inhabited caves, and his implements appear to be mainly composite, that is, set in a wooden handle, as the stone artefacts are too small for use as single weapons. These stone artefacts usually occur at two levels, those of the lower being twice as large as those from the upper, which also possesses a greater number of types. The culture failed to develop so far as that of India, and the art of grinding and polishing was almost unknown. Generally, the implements are little worked if made of quartz; but occasional pigmy implements are as delicately finished as Solutrean. The name Balangoda is proposed for this culture, after the cave from which the implements are best known. The common type of pottery found in the deposits has a wicker or mat-basket design, but another form, probably prehistoric, has a wicker-loop design on the inner surface. Certain types of potsherd found in both neolithic and protohistoric appear to have survived with little variation down to modern times. Pieces of hæmatite show flat surfaces where they have been ground for pigment. Bone splinters ground to a point at one or both ends were possibly used as borers, needles, or for fishing.

The best prehistoric deposits occurred in caves notably difficult of access, but close to a stream which flowed down the rock near the entrance. Each cave possessed a sandy outer platform with a look-out rock, and lay under the shelter of a large overhanging shelf of rock. Neolithic man generally piled his refuse not at the cave mouth but on one side of the platform.

A number of the caves have been investigated, and from the evidence of the deposits of which details are given, it is apparent that the neolithic colony inhabiting a rock shelter comprised several families, of which the men were hunters, trappers and fishers, while the women collected fruit, nuts and shell-fish. Some degree of agriculture may have been practised. Calcined bones furnish evidence of the use of fire and the practice of roasting game.

PRODUCTION OF DRUGS WITHIN THE BRITISH EMPIRE

THE Appendix to the recently published War Memorandum by the Medical Research Council on "Economy in the Use of Drugs in War-Time" (H.M. Stationery Office. 3*d.* net) is of more durable interest than the body of the Memorandum, since it proposes a long-term plan for the cultivation of medicinal plants, whereas the special need for economy in the prescription of scarce drugs will pass with the emergency. The Appendix consists of two lists of drugs the cultivation of which in the British Empire should be encouraged. The first list relates to domestic production and the second to production in the Colonial Empire. It is not proposed to comment, in this note, on all the items named in the Appendix, but to make a few observations based upon the results of experimental work designed to ascertain whether it is feasible to cultivate economically and on a commercial scale, either at home or in some Empire country overseas, certain medicinal plants for the supply of which Great Britain has paid tribute in the past to foreign nations.

Taking first the list of drugs which the Memorandum recommends for production in the United Kingdom, it is proposed to refer to cascara sagrada, ergot, dill, gentian and lobelia. In the past the bulk of Great Britain's large imports of cascara sagrada has been supplied from forests on the American side of the north-west Pacific coast; contributions from the Canadian side have been comparatively small. Experiments have proved that the shrub from which the bark is peeled can be grown in certain soils in Great Britain as a coppice crop on a five-year rotation. An additional advantage of home cultivation is that the wood remaining after the bark has been peeled from it could be converted into charcoal equal in quality to that obtained from alder buckthorn for the manufacture of explosives.

Ergot, of which large quantities are consumed by the British drug manufacturing industry, is supplied mainly by Portugal and Spain. It could be produced in Great Britain, the most favourable places for this purpose being in the west of England and in Wales. Already plans have been laid for experiments, and research workers are devoting attention to the selection of the species and strain of the fungus. It is satisfactory to know that the danger of a serious infection of cereals other than rye is slight. The aim is to select strains of high alkaloidal content, and it may be observed that much of the information concerning the alkaloidal content dates back to the time before the discovery of the alkaloid ergometrine. Chemical methods of analysis for differentiating water-soluble alkaloid (ergometrine group) from water-insoluble alkaloid (ergotoxine group) have been devised, and it seems desirable that cultivation experiments should be controlled on this basis. Incidentally, publications from the Pharmacopœia laboratory have indicated the possibility that the official standards of the British Pharmacopœia will be eventually on this basis.

Dill, which was formerly supplied largely from Germany, can be grown as a cover crop with caraway, the dill being harvested in the first year and the caraway in the second; similarly, coriander, which is already cultivated in England, may be used as a cover crop for caraway. With regard to gentian, which in normal times was imported from Italy, Spain and France, there are definite grounds for stating that it could be grown in Great Britain, but several years are needed to develop the large roots which are preferred in the London drug market. Lobelia, the present source of supply of which is the United States, can be grown on moderate to light soils in the southern half of England.

Coming now to the list of some forty vegetable drugs and essential oil-yielding plants which the Memorandum recommends for cultivation in some parts of the British Empire overseas, it is satisfactory to know that the following are already in production in India: nux vomica, podophyllum resin, rhubarb, belladonna, digitalis, henbane, jalap, lobelia, opium, squill, senna, santonin, karaya gum, and the following oils: arachis, eucalyptus, hydnocarpus and castor. The cultivation in India of psyllium and agar could also be developed, and there seems but little reason to doubt that some of the soils and climates of India are suitable for the cultivation of some of the other substances in the list set out by the Medical Research Council.

Australia, too, and New Zealand are countries which can supply some of Britain's needs for drugs. Such substances as digitalis, ephedra, ergot, liquorice, peppermint and pyrethrum, should repay investigation by cultivation in suitable places in Australia. The leaves of a tree indigenous to Australia contain hyoscyamine and hyoscine, and should prove a valuable source of these alkaloids. New Zealand is already a potential source of digitalis; it is produced there in commercial quantities. The species of fungus which grows on Festuca ergot in New Zealand is esteemed as a source of ergotamine. Many other drugs in the list could be grown economically in that Dominion. Canada has not been a fruitful source of vegetable materia medica, but there is little doubt that some of the drugs which are supplied by the United States could be cultivated successfully in Canada. Another British country which has given good promise as a source of vegetable drugs is Kenya, and it is understood that official encouragement will continue to be given to experimental stations in this colony.

FORTHCOMING EVENTS

Monday, March 31

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 5 p.m.—Mr. S. H. Beaver: "Railways of the Balkan Peninsula".

Wednesday, April 2

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Rt. Hon. Lord Horder: "The Modern Troglodyte".

Institution of Naval Architects (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2). Eighty-second Annual Meeting.

Thursday, April 3

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 12 noon—Hundredth Annual General Meeting. 2.45 p.m.—Sir Robert Robinson, F.R.S.: "The Mechanism of the Benzidine Rearrangement and some Related Topics".

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Sir Arthur Hill, F.R.S.: "The Centenary of the Royal Botanic Gardens, Kew".

Friday, April 4

Institution of Chemical Engineers (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 11 a.m.—Nineteenth Annual Corporate Meeting. 11.45 a.m.—Presidential Address: "Some Post-War Problems".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Chemist at Thorpe Power Station—The City Electrical Engineer, 4 Duke Street, Norwich (April 2).

Teacher in the Mechanical Engineering Department—The Principal, Technical College, Wolverton, Bucks. (April 4).

Assistant Inspector (male) of Schools—The Director of Education, Education Office, Chapel Street, Salford 3 (April 5).

Principal of the Cardiff Technical College—The Director of Education, City Hall, Cardiff (April 7).

Headmaster for St. John's School, Concepcion, Chile—The British Council, 3 Hanover Street, London, W.1 (quoting 'Concepcion') (April 9).

Master for St. Julian's School, Carcavelos, Portugal, to teach Mathematics and Elementary Science—The British Council, 3 Hanover Street, London, W.1 (quoting 'Portugal') (April 9).

Assistant Lecturer in the Department of Physiology—The Secretary, The University, Edmund Street, Birmingham 3 (April 25).

REPORTS AND OTHER PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Freshwater Biological Association of the British Empire. Scientific Publication No. 4: A Key to the British Water Bugs (Hemiptera-Heteroptera, excluding Corixidae), with Notes on their Ecology. By Dr. T. T. Macan. Pp. 36. (Ambleside: Freshwater Biological Association of the British Empire.) 1*s*. 6*d*. [192

India at War: a Record and a Review, 1939–1940. By Sir George Dunbar. Pp. 32. (London: H.M. Stationery Office.) 2*s*. 6*d*. net. [192

ASPECTS OF RECONSTRUCTION—I

THE importance already attached by the Government to post-War reconstruction was seen in the changes in the machinery of government recently announced. Mr. Arthur Greenwood, the Minister without Portfolio, has now relinquished his oversight of the economic field and, while remaining in the Cabinet, has undertaken responsibility for the study of reconstruction and post-War problems. Later on, it is stated, when the end of the War can be more clearly foreseen, a ministry will be formed for this purpose. Meanwhile, Mr. Arthur Greenwood will be chairman of the group of Ministers.

In the attention which has been focused on the question of production and man-power and the effect of the changes simultaneously announced in that field, this part of the statement has been somewhat overshadowed. The statement, however, points out that the object will be to find practical solutions for the immediate problems of a transition from war to peace, and also to outline and presently to amplify a policy for the years immediately following the War which will command the support of the nation as a whole and enable united action to proceed in peace as in war. Mr. Greenwood has himself described some of the problems that he and his colleagues have specially in mind, and it is worth noting that he brings to this task the experience that he gained in the War of 1914–18. He was an active and resourceful member of the first Reconstruction Committee set up by Mr. Asquith's Government in 1916, and then of the Ministry of Reconstruction set up by Mr. Lloyd George in 1917.

Mr. Greenwood has said that the country will not tolerate the spectacle of abject poverty or the curse of unemployment. Our educational system and our social services will be developed, and plans are being made to abolish ugliness and hovels in our towns. Mr. Greenwood has spoken, too, of his desire that the free spirit of man should emerge from the ruins of the War, and referred to the problem of unemployment. In remoulding our economic system it must indeed be a prime concern to preserve and increase the enjoyment of those rights and liberties that have been overthrown in the totalitarian States, and which we have entered on this struggle to uphold.

There is abundant evidence that Mr. Greenwood and his colleagues are not thinking ahead of the nation, but are giving expression to thoughts and aspirations occupying the minds of many already in the midst of their concentration on the immediate task of winning the war. The undercurrent of questionings with which Lord Reith's appointment as Minister of Works and Building was received, and the type of informed criticism which has greeted his appointment of Mr. T. S. Tait as director of standardization, show the live interest which is already taken in this question of reconstruction. Other noteworthy examples are to be seen in the address on "Trends in Nutrition" given by Sir John Orr before a meeting of the Leeds Branch of the British Medical Association last autumn, and recently published in the *British Medical Journal*, the fine address on "Problems of Building Reconstruction" delivered by Mr. D. E. E. Gibson, the city architect, Coventry, before the Royal Society of Arts early last December, and the admirable report of the Committee of the Town Planning Institute on Compensation and Betterment.

An outstanding discussion of the wider issues of reconstruction has been contributed to the

Round Table of January under the title "Reconstruction : Ends and Means", which as a contribution to lucid thinking about this important matter deserves widespread attention and has real claims on the notice of scientific workers. It demonstrates why this marked growth of the readiness to re-examine the foundations of our society is timely and should be encouraged, and gives us yet another weighty reminder that, as the experience of the last Ministry of Reconstruction showed, reconstruction must be planned now or never. It is not true that the opportunity will come when the victory is won ; the opportunity will then disappear. It is the fires of war that have softened the framework of our society, and we must strike while the metal is malleable if we are to determine its new shape.

There are, of course, many things that are physically unattainable in war-time, but this article in the *Round Table* makes once more the point that has been repeatedly urged in these columns : plans for reconstruction—provided they reflect the unity of the nation and do not disturb it—are not a hindrance to the strategists ; they are a necessary part of the grand strategy of victory, both at home and abroad. In them we can take a spiritual offensive, and proving among our own people that democracy is a cause as bold and dynamic, as young and as forceful as any tyrant's 'New Order', we shall not have to coax allies to our standard.

This note, so clearly sounded in President Roosevelt's inaugural address on January 20, shows indeed where the strongest hope of enduring Anglo-American co-operation lies, and how much a bold and creative policy of reconstruction might do to secure American support in the wider task of international economic reconstruction after the War. Moreover, the article shows how little reason there is to be pessimistic about our powers of recovery or resources for reconstruction. Productive resources are unlikely to be materially reduced, and the immensely lighter toll of life which the first sixteen months of the War have claimed as compared with experience in 1914–18, to which the Prime Minister recently referred in dealing with our man-power resources, suggests that our position is likely to be stronger rather than weaker than in 1918, because the real capital of the nation, its man-power and woman-power and the moral and spiritual resources, are less impaired whatever the material destruction.

It has been suggested that at present it is the sorts of reconstruction that require clear definition rather than the sketching of any specific measures. There is anxiety that action taken in war should not, if at all avoidable, prejudice the future. Moreover, we are developing our organization and our plans for obliterating the damage due to air raids. Even this reconstruction in the literal sense of the word is not a simple job. Someone must at least decide which buildings shall be rebuilt first. Moreover, since we shall not generally have the opportunity of starting again from the beginning, the only real choice is between a good job and a bad job of patching. The need for very careful forethought and planning is accordingly all the greater, and even in this small subdivision of the whole question of reconstruction, the problems are immense and afford Lord Reith a magnificent opportunity.

To the extent of those opportunities the address of Mr. D. E. E. Gibson, already mentioned, bears striking testimony. Social and economic changes of far-reaching significance are already taking place, and if we are to use the opportunities which they and the destruction due to air attack afford, some of the thinking involved in planning must be done now. Moreover, if we postulate as a material ideal the right of every man and woman to a healthy and beautiful environment, national as well as local planning is required.
